R. CLAY, SONS, AND TAYLOR, PRINTERS
BREAD STREET HILL

INDEX

- Abbe (Prof. Cleveland), Structure of the Corona, 367
 Actinic Power of the Electric Light, 444, 462
 Admiree, The, 195, 442, 460, 480, 500
 Adams (A. L., M.B.), Natural History of Egypt and Malta, 280
 Adams (Prof. W. G.), Study and Teaching of Mechanics, 389
 Adaptive Colouration of Mollusca, Prof. E. T. Morse on, 408, 443
 Admiralty Manual of Scientific Inquiry, 260
 Adulteration of Food, 225
 Aerial Navigation, 334
 Agassiz (Prof.), his Exploring Expedition, 152, 170, 194, 272, 333, 342, 370, 488, 489; elected Associate of the Académie des Sciences, 369
 Agassiz (Elizabeth and Alexander), "Seaside Studies in Natural History," 198
 Agriculture, United States Department of, 197
 Airy (Prof. G. B.), Encke's Comet, 76; Computed Length of Waves of Light, 93; his Address as President of the Royal Society, 110, 111; Treatise on Magnetism, 120; elected Associate of the Académie des Sciences, 369; on a Proposed Physical Observatory, 497
 Alcohol and Tobacco Consumed in France, 89
 "Alcohol, On the Elimination of," by A. Dupré, 274
 Alder Memorial Fund, 272
 Aids (T. S., M.A.), "Text Book of Geometry," 23; Species Viewed Mathematically, 134
 Aige of Rhode Island, 250
 Allbutt (T. C., M.A., M.D.), "On the Use of the Ophthalmoscope," 3
 Allen (J. A.), "Mammals and Winter Birds of Florida," 58
 Alimentation, Economical, during the Siege of Paris, 45
 Amber, Unripe, 132
 America: Mammals and Winter Birds of Florida, 58; Dr. Habel's Explorations, 68; Academy of Sciences, Havana, 69; Harvard University, 348; Academy of Sciences, Chicago, 68, 232; Academy of Natural Science, Columbia, 70; Franklin Institute, Philadelphia, 85, 133, 391, 453, 492; Chicago Museum, 68, 88; Report on Mines and Mining, 112; Microscopical Society of Illinois, 131; Report on Patents, 132; Prof. O. C. Marsh's Explorations, 152; Museum of Natural History, New York, 152, 210; Morelet's Travels, 159; Prof. E. P. Cope's Explorations, 170; Government Department of Agriculture, 197; Rock Inscriptions in Ohio, 212; Dr. Walsh's Entomological Collection, Chicago, 250; Academy of Arts and Sciences, 271; Lehigh University, Penn., 349; Science in, 191, 251, 293, 391, 411, 412, 492, 510; Scientific Intelligence from, 414, 489; Medical Society of New York, 232
 American Association for the Advancement of Science; Meeting at Indianapolis, 13, 15, 153, 171, 212, 233, 252, 293; Prof. Hunt's Address, 329
 American Deep-Sea Soundings, Cruise of the *Mercury*, 311, 324
 American Journal of Science and Art, 273
 American Eclipse Expedition, 322
 American Naturalist, 313, 372, 473, 510, 513
 American War-Office Reports, 475
Anacharis Canadensis, 204
 Anaxia, Vestiges of the Glacial Period, 444
 Anatomy, Comparative, W. M. Ord, M.B., on, 79
 Anatomy, Comparative, by E. O. Schmidt, 298
 Anatomy and Physiology, Journal of, 293
 "Anatomy of Vertebrated Animals, Manual of the," by Prof. T. H. Huxley, LL.D., F.R.S., 245
 Annulosa, Segmentation of, 442
 Anthropological Institute, 55, 94, 134, 174, 195, 231, 315, 374, 396, 415, 442
 Anthropological Institute of New York, 250
 Anthropometry, by Ad. Quételet, 258
 Antimony, Phenomenon in a Compound of, 31
 Appalachian Mountains, Geognosy of the, by Prof. T. Sterry Hunt, 14, 32, 50
 Aquarium at the Crystal Palace, 50, 518; at Naples, 437; at Brighton, 448; at Manchester (proposed), 487
 Ararat, Ascent of, 190
 Archaeology, Peabody Museum, 32 (*And See Biblical Archaeology*)
 Arctic Exploration, C. R. Markham, F.R.G.S., on, 77; by Capt. Hall, 88, 112; Dr. John Rae, F.R.G.S., on, 110, 165; Changes in Circumpolar Lands, 162, 225, 242
 "Arithmetic, Methods of Teaching," by J. G. Fitch, 99, 191
 Arithmetic and Mensuration, by C. W. Merrifield, F.R.S., 299
 Armstrong (Frank), the Typhoon of Sept. 2, 1861, 166
 Artesian Wells in London and Paris, 432, 453
 Artificial Milk, 45; W. M. Williams, F.C.S., on, 129
 Asia Minor, Geography of, 430
 Association for the Improvement of Geometrical Teaching, 401, 430
 Association for the Advancement of Science, a French, 357
 Astronomical Society, 76, 310, 497; President's Address, 433
 Astronomy, Lectures and Examinations at Rugby, 448
 "Astronomical Phenomena in 1872," by W. F. Denning, 261
 "Astronomische Tafeln und Formeln," by Dr. C. F. W. Peters, 240
 Atmosphere, its Spectrum, 341
 Atmosphere, Luminous Matter in the, 304
 Atmosphere, Universal, 5
 Aurora of Feb. 4, 1872, as seen at Edinburgh, Rugby, Shanklin, Ireland, Gloucester, Tottenham, Dublin, Barnstaple, Guildford, 282-285; France, Wales, Scotland, Alexandria, Turkey, Egypt, 292; Hereford, Twickenham, Cumberland, 302; Hay, Guildford, St. Leonards, Stonyhurst, Charnbury, 303; Ireland, 304; Berlin, 324; India, 371, 450; Nashville, U.S., 400; Cape of Good Hope, 443; Ohio, 444; Iceland and Faro, 461; St. Thomas, Alabama, 461; J. P. Earwaker on, 322; Prof. Respighi on, 511; J. T. Bottomley on, 326; Report by C. Meldrum, F.R.A.S., Mauritius, 392; Col. G. Greenwood on, 400; Magnetic Disturbances, 356
 Aurora of Feb. 4, 1871, and Earth Currents, W. H. Preece on, 368
 Aurora Borealis of Nov. 9 and 10, 1871, 43, 61; at Montreal, 431; Douglas, Isle of Man, 155; New Haven, 172; Pinner, 251; Bedford, 481
 Aurora Borealis, its Spectrum, 172, 326
 Auroras, Height of, T. W. Backhouse on, 422
 Auroral Statistics, Prof. C. P. Smyth, F.R.S., on, 301
 Aurora Islands, New Hebrides, S. J. Whitmee on, 365
 Austria; Academy of Sciences, Vienna, 32; Imperial Geological Institution, Vienna, 176, 216, 276, 376, 498
 Australia; Royal Society, Victoria, 32; Observatory, Victoria, 191; Melbourne University, 348; Dr. Krefft on its Natural History, 349; Clouds of Locusts, 411; Kangaroo Rats, 70; Eclipse Expedition, 205, 290, 351; Fossil Mammals of, 503; Scientific Researches by the Eclipse Expedition, 351
 Australian Spiders, 262
 Avebury, Druidical Circle at, 347
 Babbage (Charles, F.R.S.), Obituary Notice of, 28
 Backhouse (T. W.), Is Blue a Primary Colour? 25; Height of Auroras, 422
 Baily (W. H., F.G.S.), "Figures of British Fossils," 151; the Kiltoran Fossils, 224
 Baird (Dr. W. F.R.S.), Obituary Notice of, 271, 291
 Ball (J., F.R.S.), Chance of Survival of New Varieties, 263
 Balloon Navigation, Dupuy de Lôme on, 334
 Barker (G. F.), Spectrum of the Aurora, 172
 Barometer, Low Pressure in Polar Regions, 102
 Barometric Depressions, Development of, 343, 364, 382, 400, 422, 461

- Barometric Variations, Fixed, 407
 Barrett (W. F., F.C.S.), Colour of a Hydrogen Flame, 461;
 Phenomena associated with it, 482
 Barry (Philip), New Form of Sensitive Flame, 29
 Bastian (Prof. H. C., F.R.S.), Origin of Monads, &c., 454
 Batavia, Volcano at Ternate, 272
 Beale (Dr. Lionel S., F.R.S.) Difficulties of the Darwinian
 Theory, 63, 142, 183; on the Relation of Nerves to Pigment,
 373
 Beet-root Sugar, 32
 Bekul, Eclipse Observations at (*With Illustrations*), 265
 Belfast Natural History Society, 31
 Belfast Naturalists' Field Club, 211
 Belgium; Royal Academy of Sciences, 173, 391; Coalfields,
 491
 Belgrand (M.), "Le Bassin Parisien aux Ages Antéhistoriques,"
 377
 Bell (Rev. W. R.), the word "Whin," 383
 Bennett (Prof.), Physiology for Women, 73
 Bennett (A. W., F.L.S.), Homoplasy and Mimicry, 12; Aurora
 Borealis of Nov. 9 and 10, 1871, 61; Darwin's "Origin of
 Species," 318
 Benson (W.), Is Blue a Primary Colour? 25
 Berkeley (Rev. M. J., F.L.S.), Alternation of Generation in
 Fungi, 122
 Berthou Dynamometer, Rev. T. W. Webb, F.R.A.S., on, 6
 Biblical Archaeology, Society of, 55, 134, 214, 315, 396, 495
 "Bird Life," by Dr. A. E. Brehm, 180
 Birds' Wings, Mechanism of Flexion and Extension in, 233, 244
 Birkbeck Literary and Scientific Institution, 210
 Blackie (G. S., M.D.), Aurora of Feb. 4, 1872, 400
 Blind Animals of the Mammoth Cave, Kentucky, 445, 484
 Blind Fish (*Amblyopsis spelæus*), 305
 Blood Crystals, 393
 Blood Spectrum, 7
 Blue, the Colour, 25
 Boesinger (J.), Eclipse, as seen at Ootacamund, 300
 Bones of Birds, Carpal and Tarsal, 293
 "Botany, Contributions to," by J. Miers, F.R.S., F.L.S., 42
 "Botany, The Young Collector's Handy-Book," by Rev. H. P.
 Dunster, 201
 Botany as a Branch of Education, 263
 Botany, Professorship at the Horticultural Society, 331
 Botany, Speke and Grant's African Collection, 391
 Bohe (Dr. Ferdinand), "Physikalisches Repetitorium," 141
 Bottomley (J. T., F.R.S.E.), Melting and Regelation of Ice,
 185; Aurora of Feb. 4, 1872, and New Declinometer, 326
 Brazil, Discoveries by Prof. C. F. Hartt, 391
 Brehm (Dr. A. E.), "Bird-Life," 180
 Brigham (W. T., M.A., A.A.S.), "Earthquakes of New Eng-
 land," 240
 Brighton Aquarium, 443, 469
 Bristol Naturalists' Society, 69, 511
 Bromberg (F. G.), Aurora of Feb. 4, 1872, 461
 B. others (A.), his Photograph of Mr. Proctor's Star Map, 50, 70
 Brown Institution for Diseases of Animals, 138, 202, 292
 Buchan (A.), Aurora of Feb. 4, 1872, 461
 Budd (J.), Beautiful Meteor seen at Waterford, 382
 Buff (Dr. Heinrich) on Mechanics, 41
 Bulls, Influence of Violet Light on their Development, 268
 Burton (Capt. Richard F.), "Zanzibar," 338
 Butterflies, Flight of, 101
 Butterflies of North America, 490
 Calcutta, Sanitary Improvements in, 150
 Cattle, Dome-tic Breeds of, 155
 Cannisarro (Prof.), Faraday lecture by, 468
 Carboniferous Forest (*With Illustration*), 306
 Carpenter (Dr. W. B., F.R.S.), Oceanic Circulation, 59, 143,
 161
 Carpenter, Dr., and Dr. Mayer, by Prof. J. Tyndall, F.R.S., 143
 Carpenter (J., F.R.A.S.), Preparations for the approaching
 Transit of Venus, 177
 Carpenter (W. L.), Deep-Sea Soundings, 341
 Carruthers (W., F.R.S.), Kiltoran Fossils, 184, 242, 254
 Cambridge, Science at, 9, 49, 81, 131, 151, 231, 269, 290, 310,
 370, 429, 487, 510; Geology of the neighbourhood, 314;
 Philosophical Society, 310, 416, 515; R. R. Webb, Senior
 Wrangler, 271
 Campbell (Dr.), Natural History of Eastern Thibet, 406
 Camphor Group, Compounds of the, 393
 Cancer, Use of Condurango in, 243
 Cane Sugar, 170
 Cape of Good Hope; Flora Capensis, 311
 Capron (T. R.), Aurora Borealis of Feb. 4, 1872, 284, 303
 Ceteosaurus in the Great Oolite near Oxford, 148
 Chance of Survival of New Varieties, by J. Ball, F.R.S., 263
 Change of Habits in Animals and Plants, 262
 Changes in Circumpolar Lands, 162, 225, 242
Cheironectes pictus, 501
 "Chemical Notes," by T. Wood, Ph.D., F.C.S., 398
 Chemical Society, 173, 195, 213, 256, 296, 335, 373, 395, 468,
 474, 492, 513, 514
 Chemi-try, Inorganic, Class-Book, by D. Morris, B.A., 282
 Chemistry, Waynflete Professorship at Oxford, 291
 Cherbourg Society of Natural Sciences, 394
 Chesney (Colonel, F.R.S.) Obituary Notice of, 291
 Chester Society of Natural Science, 40
 Chicago, Destruction of the Academy of Sciences and Museum,
 68, 88, 232; Dr. Walsh's Entomological Collection, 250;
 Observatory, 320
 China, Typhoon of Sept. 2, 1871, 166
 Christison (Prof. Sir Robert, Bart.), Notice of, 49
 Christ's Hospital, 312, 449
 Chromosphere, Catalogue of Bright Lines in its Spectrum, 312
 Cinchona Plantations in India, 349
 Circumpolar Lands, Changes in, 162, 225, 242
 Circumpolar Lands, J. J. Murphy, F.G.S., on, 285; G. Hamil-
 ton on, 321; H. H. Howorth on, 420
 Civil Engineers, Institution of, 50
 Classification of Fruits, 6
 Clifton College Museum, 190; Scientific Society, 371
 Climate of Ceylon, 412
 Climate of Uckfield, 419
 Climbing Plants, 192
 Close (Rev. M. H.), Aurora Borealis of Feb. 4, 1872, 284
 Cloud, New Form of, 7
 Clouds, Formation of, 398, 462
 Coal, in Chile, 171, 412; Ireland, 162; Costa Rica, 211
 Coal Measures and Coal Supply, 470, 490
 Cobra and Mongoose, Fight between, 204, 305
 Colding (Prof.) on the Laws of Currents, 71, 90, 112
 Coleoptera of Scandinavia, 99
 College of Surgeons and Physicians, Conjoint Examination
 Scheme, 9, 170, 209
 College of Surgeons, 291
 Colliery Explosions and Weather, 504
 Colloid Matters, their Influence on Crystalline Forms, 275
 Colour, Is Blue a Primary? 25
 Colour of a Hydrogen Flame, 444, 461, 481, 501
 Colouring Matters found in Fungi, 298
 Comet, Great, of 1861, 304
 Comets, their Collision with the Earth and Planets, 310
 Comparative Anatomy, 79, 298
 Complimentary Names, Use and Abuse of, 264
 Composition of Vibrations, 321
 Conchology, Dr. John C. Jay's Collections, 152; Specimens
 Destroyed in the Siege of Paris, 349
 Condurango Root, a Specific for Cancer, 211; Dr. A. Destruge
 on, 243
 Conscious Mimicry, 480
 "Consumption," by H. M. Cormac, M.D., 459
 Contact, Phenomena of, 182
 Contact of Surfaces, 334
 Cooke (M. C.), Alternation of Generations in Fungi, 108
 Cope (Edw. D., A.M.), "On the Origin of Genera," 21; Laws
 of Organic Development, 252; Survival of the Fittest, 363
 Copernicus (Nicholas), Celebration of his Birthday, 111, 151
 Copley Medallist of 1870 (Dr. J. P. Joule), by Prof. J. Tyndall,
 F.R.S., 137
 Copley Medallist of 1871 (Dr. J. R. Mayer), by Prof. J. Tyndall,
 F.R.S., 117
 Corals, Deep-Sea, Count de Pourtales on, 121
 Coral Islands in North Pacific Ocean, 112
 Cordoba, Argentine Republic, Observatory at, 272, 309
 Cornwell (Jas. Ph.D.), and J. G. Fitch, M.A., their Works
 on Arithmetic, 99
 Corona, Structure of the, 367
 Coues (Dr. Elliott), Flexion and Extension of Birds' Wings, 233
 Coughtrey (D. M.), Flexion and Extension of Birds' Wings, 244

- Cranial Measurements, 463
 Crannogs in the South of Scotland, 203
 Creators of Science, 62, 81
 Croll (J., F.G.S.), Ocean Currents, 201, 263, 399, 502
 Croll (J., F.G.S.), Wollaston Donation Fund Awarded to, 355
 Crustaceans in the Mammoth Cave, Kentucky, 445, 484
 Crystalline Rocks, Origin of, 14, 50, 32
 Crystal Palace Aquarium, 50, 510
 Crystal Palace School of Art, Literature, and Science; Lectures on Solar Physics by J. Norman Lockyer, F.R.S., 369
 Cuckoo and Pipit: Ejection from the Nest, 383
 Cuckoo's Eggs, 501
 Cyclone in the West Indies, 507
- Dall (Wm. H.), his Survey of Alaska, 332
 Dana (Prof. J. D.), Prof. Hunt's Address to the American Association, 329; Wollaston Medal awarded to, 365; Supposed Legs of Trilobites, 393
 Danks's Rotary Iron-puddling Machine, 317, 430, 468
 Darmstadt Polytechnic School, 368
 Darwin (Chas., M.A., F.R.S.), "Origin of Species," 6th edition, 318
 Darwinian Difficulties, 63, 101, 142, 183
 Davis (A. S.), Origin of Species, 161
 Davis (Henry), Eclipse Photography, 321
 Davis (Capt. J. E., R.N.), Deep-Sea Thermometers, 124
 Davison (W.), New Zealand Forest Trees, 84
 Dawkins (Wm. Boyd, F.R.S.), Origin of our Domestic Breeds of Cattle, 155
 Dawson (George), Germ Theory of Disease, 84
 Dawson (Lieut. R.N.), Leader of the Livingstone Expedition, 250
 Day (Dr. G. E., F.R.S.), Obituary Notices of, 290, 383
 Day (E. C. H.), The Foundation of a Technological Education, 233
 De Chaumont (F.), Etymology of "Whin," 399
 Declinometer, New Form of, 326
 Deep Sea Corals, 121
 Deep-Sea Dredging, 8, 103, 204, 272, 343, 430, 449
 Deep-Sea Soundings, from the American School-ship *Mercury*, 324; W. L. Carpenter on, 341
 Deep-Sea Thermometers, Captain J. E. Davis, R.N., on, 124
 De Fonvielle (W.), Aerostation, 156, 196, 235
 Denning (Wm. F., F.R.A.S.), The Planet Venus, 100; "Astronomical Phenomena in 1872," 261
 De La Rue (Warren, D.C.L., F.R.S.), Periodicity of Sun-Spots, 192; Planetary Influence on Solar Activity, 423; Solar Physics, 493
 De Lôme (Dupuy), Aerial Navigation, 334
 Dunster (Rev. H. P.), "Young Collector's Handy Book of Botany," 201
 Descartes, "Animated Machines," 62
 Deschanel's Natural Philosophy, by Prof. Everett, 339
 Destrugre (Dr. A.), The Condurango Plant, 243
 Development of Barometric Depressions, 364, 382
 Deviation of the Compass in Iron Ships, 479
 Devon and Cornwall Natural History Society, 191
 Diamond Fields of South Africa, 74
 "Differential Equations, New Method of Integrating," by S. Earnshaw, M.A., 199
 "Discovery of a New World of Being," 380
 Dissipation of Energy, 322
 Dix (S.), Aurora of Feb. 4, 1872, 461
 Dohrn (Dr. Anton), The Foundation of Zoological Stations, and the Aquarium at Naples, 277, 437
 Drach (S. M.), Jewish Lunar Calendar, 204
 Draper (Henry, M.D.), Deep-Sea Soundings from the School-ship *Mercury*, 324
 Dredging (*See* Deep-Sea Dredging)
 Dublin: Trinity College, 49; Royal Horticultural Society, 50; Royal Geological Society, 95, 176, 315, 514; Royal Geographical Society, 173; Zoological Society, 176; Royal Dublin Society, 156; Royal Irish Academy, 95, 156, 175, 332, 375; Royal College of Science, 271, 448; Natural History Society, 394, 456
 Dudgeon (Dr.), Optical Construction of the Eye, 155
 "Dudley Observatory, Annals of the," 250
 Dumb Madness in Foxhounds, 132
 Duncan (Prof. P. M., F.R.S.), Lectures to Women on Physiology, 49
 Dunkin (Edwin, F.R.A.S.), Chicago Observatory, 320
 Dupré (A.), Elimination of Alcohol, 274
- D'Urban (W. S. M.), Eagle Ray taken in Torbay, 103
 Dyer (Prof. W. T. Threlton, F.L.S.), Structure of Lepidodendron, 25, 45; Mayer and De Saussure, 181; Natural Science at Oxford, 301; Appointed Professor of Botany at the Royal Horticultural Society 331; Lectures on Flowers and Fruits, 429
 Dynamo-Electric Light, 172
- Eagle Ray taken in Torbay, 103
 Earnshaw (S., M.A.), "Partial Differential Equations," 199
 Earth: The Elevation of Mountains and Volcanic Action, 381; Constitution of its Crust, 81; Its Internal Fluidity, 257; Its Magnetic Force at Bombay, 274; Its Rigidity, 223, 242, 288
 Earth Currents and the Aurora of Feb. 4, 1872, 368
 Earth Currents and Telegraphy, 212
 Earthquakes: In Barmah, 7; Constantinople, Peru, 14; Philippine Islands, 84; Bombay, 89; Panama, 90; Smyrna, Macedonia, Nicaragua, 132; New Jersey, 152; Valparaiso, Salvador, North Chile, 211; Celebes, 225; Oran, 251; Caucasus, Chile, India, 349; Saxony, 391; Valparaiso, Peru, Patna, Broossa, Darjeeling, Ahmedabad, Guayaquil, 412; Philippine Islands, 422; Salvador, Simla, Macedonia, Iquique, Malaga, 511; America, Dresden, Antioch, 511
 Earthquake in Cachar, its Secondary Effects, 513
 Earthquake Phenomena, Robert Mallet on, 261
 "Earthquakes of New England," by W. T. Brigham, A.M., A.A.S., 240
 "Earthquakes, Volcanoes, and Mountain Building," by J. D. Whitney, 240
 Ears, Prof. Laycock's Lecture on, 411
 Earwaker (J. P.), on the Aurora of Feb. 4, 1872, 322
 Eastbourne Natural History Society, 70
 Eccentricity of the Earth's Orbit, 422
 Eclipse, Solar, of Dec. 12, 1871: "Instructions for Observer," 18; The English Expedition, 30, 68, 88, 130, 150, 163, 169; French Expedition, 190; Observations in Batavia, 199; Australian Expedition, 205, 290, 351; Observations of R. N. Taylor, 222; J. Norman Lockyer, F.R.S., 217, 259, 265; Captain Maclear, R.N., 219; M. Janssen, 231, 249; Prof. L. Repighi, 237; Magnetic Disturbances, 269, 285; Observations at Ootacamund, 300
 Eclipse, Solar, American Expedition, 322
 Eclipse Photography, Henry Davison on, 321
 Economical Alimentation during the Siege of Paris, 45
 Edgar (J. H., M.A., and G. S. Pritchard), Solid or Descriptive Geometry, 80
 Edinburgh: Industrial Museum, 310; Museum of Science and Art, 169; Botanical Society, 169; Naturalists' Field Club, 116; Royal Observatory, 191, 317; Royal Physical Society, 214, 315, 375, 515; Royal Society, 335, 515; School of Art, 411; Royal College of Surgeons, 50; University, 50, 68, 73, 97, 131, 210, 292
 Edmonds (J. W.), Mongoose and Cobra, 305
 Egypt, Natural History of, by A. L. Adams, M.B., 280
 Egypt, a Trilingual Stone found at, 412
 Electrical Eel, 315
 Electric Currents, 354
 Electric Light during the Siege of Paris, 131; South Foreland Lighthouse, 251; Actinic Power, 444, 463
 "Electric Telegraph, Description of an," by Sir Francis Ronald, F.R.S., 59
 Electro-Magnetism. (*See* Mayer, Dr. J. R., and Joule, Dr. J. P.)
 Electrophysiology, by Dr. C. B. Radcliffe, 186, 206, 226
 Elger (T. G. E.), Aurora seen at Bedford, 481
 Ellery (Rob. L. J., F.R.S.), Australian Eclipse Expedition, 205
 Elliott Brothers, on Tide Gauges, 501

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for eye."—WORDSWORTH

THURSDAY, NOVEMBER 2, 1871

ripples and waves*

YOU have always considered cohesion of water (capillary attraction) as a force which would seriously disturb such experiments as you were making, if on too small a scale. Part of its effect would be to modify the waves generated by towing your models through the water. I have often had in my mind the question of waves as affected by gravity and cohesion jointly, but have only been led to bring it to an issue by a curious phenomenon which we noticed at the surface of the water round a fishing-line one day slipping out of Oban (becalmed) at about half a mile an hour through the water. The speed was so small that the lead kept the line almost vertically downwards; so that the experimental arrangement was merely a thin straight rod held nearly vertical, and moved through smooth water at speeds from about a quarter to three-quarters of a mile per hour. I tried boat-hooks, oars, and other forms of moving solids, but they seemed to give, none of them, so good a result as the fishing-line. The small diameter of the fishing-line seemed to favour the result, and I do not think its roughness interfered much with it. I shall, however, take another opportunity of trying a smooth round rod like a pencil, kept vertical by a lead weight hanging down under water from one end, while it is held up by the other end. The fishing-line, however, without any other appliances proved amply sufficient to give very good results.

What we first noticed was an extremely fine and numerous set of short waves preceding the solid much longer waves following it right in the rear, and oblique waves streaming off in the usual manner at a definite angle on each side, into which the waves in front and the waves in the rear merged so as to form a beautiful and symmetrical pattern, the tactics of which I have not been able thoroughly to follow hitherto. The diameter of the "solid" (that is to say the fishing-line) being only two or three millimetres and the longest of the observed waves five or six centimetres, it is clear that the waves at distances in any directions from the solid

exceeding fifteen or twenty centimetres, were sensibly unforced (that is to say moving each as if it were part of an endless series of uniform parallel waves undisturbed by any solid). Hence the waves seen right in front and right in rear showed (what became immediately an obvious result of theory) two different wave-lengths with the same velocity of propagation. The speed of the vessel falling off, the waves in rear of the fishing-line became shorter and those in advance longer, showing another obvious result of theory. The speed further diminishing, one set of waves shorten and the other lengthen, until they become, as nearly as I can distinguish, of the same lengths, and the oblique lines of waves in the intervening pattern open out to an obtuse angle of nearly two right angles. For a very short time a set of parallel waves some before and some behind the fishing-line, and all advancing direct with the same velocity, were seen. The speed further diminishing the pattern of waves disappeared altogether. Then slight tremors of the fishing-line (produced for example by striking it above water) caused circular rings of waves to diverge in all directions, those in front advancing at a greater speed relatively to the water than that of the fishing-line. All these phenomena illustrated very remarkably a geometry of ripples communicated a good many years ago to the *Philosophical Magazine* by Hirst, in which, however, so far as I can recollect, the dynamics of the subject were not discussed. The speed of the solid which gives the uniform system of parallel waves before and behind it, was clearly an absolute minimum wave-velocity, being the limiting velocity to which the common velocity of the larger waves in rear and shorter waves in front was reduced by shortening the former and lengthening the latter to an equality of wave-length.

Taking $\cdot 074$ of a gramme weight per centimetre of breadth for the cohesive tension of a water surface (calculated from experiments by Gay Lussac, contained in Poisson's theory of capillary attraction, for pure water at a temperature, so far as I recollect, of about 9° Cent.), and one gramme as the mass of a cubic centimetre, I find, for the minimum velocity of propagation of surface waves, 23 centimetres per second.* The mini-

* One nautical mile per hour, the only other measurement of velocity, except the French metrical reckoning, which ought to be used in any practical measurement, is 51·6 centimetres per second.

* Extract from a letter to Mr. W. Froude, by Sir W. Thomson.

mum wave velocity for sea-water may be expected to be not very different from this. (It would of course be the same if the cohesive tension of sea water were greater than that of pure water in precisely the same ratio as the density.)

About three weeks later, being becalmed in the Sound of Mull, I had an excellent opportunity, with the assistance of Prof. Helmholtz, and my brother from Belfast, of determining by observation the minimum wave velocity with some approach to accuracy. The fishing-line was hung at a distance of two or three feet from the vessel's side, so as to cut the water at a point not sensibly disturbed by the motion of the vessel. The speed was determined by throwing into the sea pieces of paper previously wetted, and observing their times of transit across parallel planes, at a distance of 912 centimetres asunder, fixed relatively to the vessel by marks on the deck and gunwale. By watching carefully the pattern of ripples and waves, which connected the ripples in front with the waves in rear, I had seen that it included a set of parallel waves slanting off obliquely on each side, and presenting appearances which proved them to be waves of the critical length and corresponding minimum speed of propagation. Hence the component velocity of the fishing-line perpendicular to the fronts of these waves was the true minimum velocity. To measure it, therefore, all that was necessary was to measure the angle between the two sets of parallel lines of ridges and hollows, sloping away on the two sides of the wake, and at the same time to measure the velocity with which the fishing-line was dragged through the water. The angle was measured by holding a jointed two-foot rule, with its two branches, as nearly as could be judged, by the eye, parallel to the sets of lines of wave-ridges. The angle to which the ruler had to be opened in this adjustment was the angle sought. By laying it down on paper, drawing two straight lines by its two edges, and completing a simple geometrical construction with a length properly introduced to represent the measured velocity of the moving solid, the required minimum wave-velocity was readily obtained. Six observations of this kind were made, of which two were rejected as not satisfactory. The following are the results of the other four:—

Velocity of Moving Solid.	Deducted Minimum Wave-Velocity.
51 centimetres per second.	23.0 centimetres per second.
38 " "	23.8 " "
26 " "	23.2 " "
24 " "	22.9 " "

Mean 23.22

The extreme closeness of this result to the theoretical estimate (23 centimetres per second) was, of course, merely a coincidence, but it proved that the cohesive force of sea-water at the temperature (not noted) of the observation cannot be very different from that which I had estimated from Gay Lussac's observations for pure water.

I need not trouble you with the theoretical formulæ just now, as they are given in a paper which I have communicated to the Royal Society of Edinburgh, and which will probably appear soon in the *Philosophical Magazine*. If 23 centimetres per second be taken as the minimum speed they give 1.7 centimetres for the corresponding wave-length.

I propose, if you approve, to call ripples, waves of

lengths less than this critical value, and generally to restrict the name waves to waves of lengths exceeding it. If this distinction is adopted, ripples will be undulations such that the shorter the length from crest to crest the greater the velocity of propagation; while for waves the greater the length the greater the velocity of propagation. The motive force of ripples is chiefly cohesion; that of waves chiefly gravity. In ripples of lengths less than half a centimetre the influence of gravity is scarcely sensible; cohesion is nearly paramount. Thus the motive of ripples is the same as that of the trembling of a dew drop and of the spherical tendency of a drop of rain or spherule of mist. In all waves of lengths exceeding five or six centimetres, the effect of cohesion is practically insensible, and the moving force may be regarded as wholly gravity. This seems amply to confirm the choice you have made of dimensions in your models, so far as concerns escaping disturbances due to cohesion.

The introduction of cohesion into the theory of waves explains a difficulty which has often been felt in considering the patterns of standing ripples seen on the surface of water in a finger-glass made to sound by rubbing a moist finger on its lip. If no other levelling force than gravity were concerned, the length from crest to crest corresponding to 256 vibrations per second would be a fortieth of a millimetre. The ripples would be quite undistinguishable without the aid of a microscope, and the disturbance of the surface could only be perceived as a dimming of the reflections seen from it. But taking cohesion into account, I find the length from crest to crest corresponding to the period of $\frac{1}{256}$ of a second to be 1.9 millimetres, a length which quite corresponds to ordinary experience on the subject.

When gravity is neglected the formula for the period (P) in terms of the wave-length (l), the cohesive tension of the surface (T), and the density of the fluid (ρ), is

$$P = \sqrt{\frac{2\rho}{T}}$$

where T must be measured in kinetic units. For water we have $\rho = 1$, and (according to the estimate I have taken from Poisson and Gay Lussac) $T = 982^* \times .074 = 73$. Hence for water

$$P = \frac{l^{\frac{1}{2}}}{\sqrt{2\pi \times 73}} = \frac{l^{\frac{1}{2}}}{21.4}$$

When l is anything less than half a centimetre the error from thus neglecting gravity is less than 5 per cent. of P . When l exceeds $5\frac{1}{2}$ centimetres the error from neglecting cohesion is less than five per cent. of the period. It is to be remarked that, while for waves of sufficient length to be insensible to cohesion, the period is proportional to the square-root of the length, for ripples short enough to be insensible to gravity, the period varies in the sesquialterate ratio of the length.

WILLIAM THOMSON

Mr. Froude having called my attention to Mr. Scott Russell's Report on Waves (British Association, York, 1844) as containing observations on some of the phenomena which formed the subject of the preceding letter to him, I find in it, under the heading "Waves of the Third Order," or, "Capillary Waves," a most interesting account of the

* 982 being the weight of one gramme in kinetic units of force-centimetres per second.

"ripples" (as I have called them), seen in advance of a body moving uniformly through water; also a passage quoted by Russell from a paper of date, Nov. 16, 1829, by Poncelet and Lesbros,* where it seems this class of waves was first described.

Poncelet and Lesbros, after premising that the phenomenon is seen when the extremity of a fine rod or bar is lightly dipped in a flowing stream, give a description of the curved series of ripples (which first attracted my attention in the manner described in the preceding letter). Russell's quotation concludes with a statement from which I extract the following:— . . . "on trouve que les rides sont imperceptibles quand la vitesse est moyennement au dessous de 25c. par seconde."

Russell gives a diagram to illustrate this law. So far as I can see, the comparatively long waves following in rear of the moving body have not been described either by Poncelet and Lesbros or by Russell, nor are they shown in the plan contained in Russell's diagram. But the curve shown above the plan (obviously intended to represent the section of the water-surface by a vertical plane) gives these waves in the rear as well as the ripples in front, and proves that they had not escaped the attention of that very acute and careful observer. In respect to the curves of the ripple-ridges, Russell describes them as having the appearance of a group of confocal hyperbolas, which seems a more correct description than that of Poncelet and Lesbros, according to which they present the aspect of a series of parabolic curves. It is clear, however, from my dynamical theory that they cannot be accurate hyperbolas; and, as far as I am yet able to judge, Russell's diagram exhibiting them is a very good representation of their forms. Anticipating me in the geometrical determination of a limiting velocity, by observing the angle between the oblique terminal straight ridge-lines streaming out on the two sides, Russell estimates it at $8\frac{1}{2}$ inches ($21\frac{1}{2}$ centimetres) per second.

Poncelet and Lesbros's estimate of 25 centimetres per second for the smallest velocity of solid relatively to fluid which gives ripples in front, and Russell's terminal velocity of $21\frac{1}{2}$ centimetres per second, are in remarkable harmony with my theory and observation which give 23 centimetres per second as the minimum velocity of propagation of wave or ripple in water.

Russell calls the ripples in front "forced," and the oblique straight waves streaming off at the sides "free"—appellations which might seem at first sight to be in thorough accordance with the facts of observation, as, for instance, the following very important observation of his own:—

"It is perhaps of importance to state that when, while these forced waves were being generated, I have suddenly withdrawn the disturbing point, the first wave immediately sprang back from the others (showing that it had been in a state of compression), and the ridges became parallel; and, moving on at the rate of $8\frac{1}{2}$ inches per second, disappeared in about 12 seconds."

Nevertheless I maintain that the ripples of the various degrees of fineness seen in the different parts of the

fringe are all properly "free" waves, because it follows from dynamical theory that the motion of every portion of fluid in a wave, and, therefore, of course, the velocity of propagation, is approximately the same as if it were part of an infinite series of straight-ridged parallel waves, provided that in the actual wave the radius of curvature of the ridge is a large multiple of the wave-length, and that there are several approximately equal waves preceding it and following it.

No indication of the dynamical theory contained in my communication to the *Philosophical Magazine*, and described in the preceding letter to Mr. Froude, appears either in the quotation from Poncelet and Lesbros, or in any other part of Mr. Scott Russell's report; but I find with pleasure my observation of a minimum velocity below which a body moving through water gives no ripples, anticipated and confirmed by Poncelet and Lesbros, and my experimental determination of the velocity of the oblique straight-ridged undulations limiting the series of ripples, anticipated and confirmed by Russell. W. T.

ALBUTT ON THE OPHTHALMOSCOPE

On the Use of the Ophthalmoscope in Diseases of the Nervous System and of the Kidneys; also in certain other General Disorders. By Thomas Clifford Albutt, M.A., M.D., Cantab. &c. (London and New York: Macmillan and Co., 1871.)

THE advances that have been made in the knowledge of the diseases of the eye since the introduction of the ophthalmoscope are now very widely known, not alone in the medical profession but to the general public. This little instrument, essentially consisting of a mirror with a hole in the centre by which a ray of light can be thrown into the interior of the eye, lighting up its recesses, and enabling, with the aid of a common hand lens, almost every portion of it to be explored, may be said to have revolutionised the surgery of the eye. Many separate and distinct types of disease have been distinguished in conditions that were formerly grouped together under the general term of amaurosis, and the ophthalmic surgeon, no longer administering, as was too often formerly the case, his remedies in rash ignorance, is now able either to infuse well-grounded hope of recovery, or to spare his patient the annoyance of protracted treatment when treatment would be hopeless. For nearly twenty years the use of the ophthalmoscope has been, as was natural, almost entirely restricted to those who devoted themselves to the study of ophthalmic diseases. Like other mechanical aids to diagnosis, as the stethoscope and laryngoscope, its employment requires practice, the opportunities for acquiring a mastery over it were till recently rare, and its value in the practice of medicine was by no means generally recognised. Within the last few years, however, several excellent surgeons and physicians, amongst whom Mr. Hutchinson, Dr. Hughlings Jackson, Dr. John Ogle, and the author of the treatise before us may be especially mentioned, have gradually begun to recognise that the ophthalmoscope may be made available not only to determine the nature of any defect of vision of which the patient may complain, but as a means of reading within certain limits changes in the conditions of the system at large, and of the nervous system in particular.

* *Memoirs of the French Institute*, 1829.

† The dynamical theory shows that the length from crest to crest depends on the corresponding component of the solid's velocity. For very fine ripples it is approximately proportional to the reciprocal of the square of this component velocity, and therefore to the square of the secant of the angle between the line of the solid's motion and the horizontal line perpendicular to the ridge of the ripple.

The work of Dr. Allbutt is, however, the first treatise in English that is occupied exclusively with the ophthalmoscopic appearances presented in cases of cerebral disease, or in other words with the diagnosis of nervous affections by the ophthalmoscope. Abroad he has been preceded by M. Bouchut, whilst the volumes of the "Archiv für Ophthalmologie" are a mine of original memoirs written by the best ophthalmologists in Germany on the bearings of ophthalmoscopic observations on nervous affections. To these, of course, Dr. Allbutt makes frequent reference. In no instance, however, have we noticed a servile adherence to the opinions of others, the statements he quotes being always checked by his own observations, and every page bearing the stamp of very careful and sound investigation. It is impossible with the limited space here at disposal, and it would perhaps scarcely be interesting to many of our readers, to give what the work really deserves, a *résumé* and discussion of its successive chapters; but we may here perhaps point out one or two of the principal points of interest.

In speaking of the disc of the optic nerve, Dr. Allbutt expresses himself in favour of the view of Galezowski, who is fortified by the observations of Leber, to the effect that the vascularity of the disc is to a great extent independent of that of the retina, and rather forms a part of the vascular system of the brain. The importance of this principle in enabling deductions to be drawn respecting the occurrence of intercranial disease is obvious. Proceeding on this hypothesis, Dr. Allbutt points out the changes that are visible in a large number of different affections. He draws a strong line of distinction between ischaemia and optic neuritis, conditions that have hitherto been almost invariably confounded by ophthalmic surgeons, but of which the former is produced by some cause, often of a mechanical nature, interfering with the return of the blood from the retina, whilst the latter is a true inflammation of the nerve. The diagnosis of the two in their earlier stages is very clearly and correctly laid down. At a later period both conditions pass into white atrophy, and it is not always then easy to pronounce which of the two has previously been present. His views, in regard to changes in the optic disc from intercranial disease, are clearly laid down in the following passage (pp. 129, 130):—"We find optic changes in connection with two kinds of intracranial disease in particular; the one tumour, the other meningitis. When we analyse the matter one degree further, we ascertain that, although the choked disc (ischaemia) and the inflamed nerve may co-exist with either of these kinds of disease, that nevertheless the choked disc is far more commonly found in association with tumour and hydrocephalus than the inflamed nerve. The inflamed nerve, on the other hand, is very commonly found in association with meningitis, and of meningitis not of the surface, nor of parts near any supposed vasomotor centres, but with meningitis near the centre." And with this we are disposed substantially to agree. Dr. Allbutt expresses himself in very doubtful terms in regard to the existence of tobacco amaurosis, and it certainly is extraordinary that, if really constituting an effect of the use of that leaf, it is not of more frequent occurrence amongst the Germans and Americans, who are much larger consumers than either the French or ourselves.

Our readers will see that Dr. Allbutt has, if not exactly opened up, at all events vigorously worked at, a new field of medical investigation. This field promises when duly cultivated to yield very valuable fruit; and, we are sure, the conclusion at which every candid reader will arrive, after carefully perusing it, will be that no physician should consider he has fully examined any case of cerebral disease unless he has accurately investigated the appearances presented by the eye under the ophthalmoscope. It is not to be supposed that Dr. Allbutt has by any means exhausted the subject. Many difficulties lie in the path of the most diligent inquirer. In many instances conditions of disease are seen to be present, as to the nature of which only a guess can be formed, and respecting which from forgetfulness or lack of observation on the part of the patient no history can be obtained; whilst in a multitude of cases the disease is seen only at one stage of its progress, and the physician is unable to ascertain, owing to his losing sight of his patient, the ulterior changes that take place.

Lastly, in many cases the prejudice of friends (a point to be greatly regretted) prevents the examination of the eyes after death. The fragmentary character of many of the reports of cases collected by Dr. Allbutt in his appendix is painfully evident, and leaves many hiatuses to be filled up by future research. We may, however, in conclusion, thank Dr. Allbutt for having published a work which constitutes an important step in the advancement of medicine, and will certainly form a very valuable guide to the profession at large, nor may we omit to thank the publishers for the excellent manner in which the book has been issued from the press.

H. POWER

OUR BOOK SHELF

Hardy Flowers: Descriptions of upwards of thirteen hundred of the most ornamental species, and directions for their arrangement, culture, &c. By W. Robinson, F.L.S. (London: F. Warne and Co., 1871.)

MR. ROBINSON is a prolific writer, but his prolificacy (as Webster has it, if Dr. Ingleby and Dr. Latham will allow us the word) does not degenerate into mere book-making. Like its predecessors, this volume is one of practical utility both to the professional gardener and to the cultivator of flowers for their beauty. Much the greater part of the volume is occupied with a descriptive list of the most ornamental hardy flowers, with directions for their culture, suitable positions, &c.; but this is introduced by some practical hints on the general subject of gardening. That Mr. Robinson has the courage to attack some time-honoured gardening customs, will be seen from the following paragraph:—"No practice is more general, or more in accordance with ancient custom, than that of digging shrubby borders, and there is none in the whole course of gardening more profitless or worse. When winter is once come, almost every gardener, although animated with the best intentions, simply prepares to make war upon the roots of everything in his shrubby border. The generally accepted practice is to trim, and often to mutilate, the shrubs, and to dig all over the surface that must be full of feeding roots. Delicate half-rooted shrubs are often disturbed; herbaceous plants, if at all delicate and not easily recognised, are destroyed; bulbs are often displaced and injured; and a sparse depopulated aspect is given to the margins, while the only 'improvement' that is effected by the process is the annual darkening of the surface of the upturned earth." After

this we find some pertinent and useful hints on the best mode of grouping hardy perennials, and the art of managing the rock-garden, the wild-garden, water, and boggy ground; on the culture and propagation of early flowers, and other subjects dear to the dweller in the country. Compared with the art of gardening as practised twenty years ago, we are certainly now in an altogether new and improved epoch, and Mr. Robinson is one of the pioneers to whom we are mainly indebted for the introduction of a better and more rational style. A. W. B.

Hints on Shore-Shooting: with a chapter on skinning and preserving Birds. By James Edmund Harting, F.L.S., &c. (London: Van Voorst, 1871.)

A GOOD sportsman, whether he knows it or not, must be more or less of a good naturalist, and this Mr. Harting is. His unpretending little book, therefore, certainly deserves mention here, and the more so since he has worthily won his spurs by making the group of birds most sought by the "shore-shooter" an especial subject of study. What he tells us is the result of his own observation, and is pleasantly told. What he does not tell us is whether "shore-shooting" has, with most people,—for we except him—any other *raison d'être* than the "fine-day-let's-go-and-kill-something" impulse. If not, we really do not see that there is much difference in principle between Pagham and Hurlingham.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

An Universal Atmosphere

I HAVE much pleasure in replying to Mr. Browning's question in NATURE, vol. iv. p. 487, as it is one that legitimately strikes at the root of all my speculations, and which, if unanswerable, conveys an objection that must demolish the whole structure I have endeavoured to erect in my essay on the "Fuel of the Sun."

If I am right, the atmospheres of the sun, the moon, the planets, or of any other cosmical body of known mass and dimensions, may be calculated in units of the earth's total atmosphere by the simple formula reasoned out in Chap. iii. of the above-named work, i.e., by multiplying the mass of the body (expressed in units of the earth's mass) by its own square root, thus

$$x = m \sqrt{m};$$

where x is the atmosphere of the body in question expressed in units of the earth's known total atmosphere, and m is the mass of the body expressed in units of the earth's mass.

The mass of the moon being $\frac{1}{80}$ of that of the earth, we get

$$\frac{1}{80} \sqrt{\frac{1}{80}} = \frac{1}{715.5416}, \text{ or, discarding fractions, the moon's atmosphere as } \frac{1}{715} \text{ that of the earth.}$$

But the diameter of the moon being to that of the earth as 0.264 to unity, the lunar surface will be to that of the earth as 0.264² or 0.0697 to 1, and the lunar atmosphere will be concentrated accordingly, bringing the mean atmospheric pressure on the lunar surface to

$$\frac{1}{0.0697} = \frac{1}{49.8355}, \text{ or } \frac{1}{50},$$

nearly of that of the earth's mean atmospheric pressure. Such an atmosphere would support a column of mercury six-tenths of an inch in height. Mr. Browning will recognise this as about equal to the best vacuum obtainable in an old-fashioned air-pump of average defectiveness.

Such is the theoretical pressure upon every part of the moon's surface, supposing the form of the moon to be a perfect spheroid of rotation with a perfectly smooth surface. But the moon is no such regular body. It presents far more irregularities in proportion to its size than would our earth if the ocean were

evaporated, and its depths laid bare so that our mountain heights should be measured from the ocean bottom. Under such conditions the bulk of even our atmosphere would occupy the ocean valleys, and very rare indeed would be the remainder that reached the mountain tops and elevated ridges of the earth. On the moon with its filmy atmosphere of only six-tenths of an inch mean pressure, the rarefaction on the high lands and mountains would be carried beyond the limits of observable refractive power under the conditions assumed—viz., of a special atmosphere merging gradually into the universal interstellar medium.

The visible edge of the moon which effects the occultation of a star must in almost every possible case be formed by the ridges and summits of the lunar mountains, in no case by the bottom of the lower valleys, for in looking horizontally across the moon's rotundity these valleys and even the maria must be foreshortened, and their lower depths walled out of the reach of our vision by the great lunar elevations. Thus the occultation of a star would occur without its previous plunging behind any outlying lunar atmospheric matter of appreciable density. We must not forget that Sir J. Herschel's calculation, which assigns one second of refraction to an atmosphere equal to $\frac{1}{9.577}$ of the density of the earth, is based on the theory of a limited atmosphere with a sharp and definite boundary suddenly terminating in a vacuum.

But this rarefaction on the elevated portions of the moon demands a compensating condensation or concentration of atmospheric matter in the valleys, crater-pits, and maria. Here the pressure on the moon's surface should considerably exceed the calculated mean. This consideration suggests a very interesting question. Would such an atmosphere, say capable of supporting one inch of mercury, produce any observable effects? If I am right in regarding water as one of the constituents of the universal atmosphere, there are good reasons for supposing that it would.

The small share of water due to the moon would all be raised far above its low boiling-point, early in the lunar day, by the heated lunar surface. There would be no sea, no clouds, no rain, no snow, but on the plains and in the valleys a formation of hoar-frost should occur at the lunar eventide, beginning just where the sun's rays become too oblique to maintain the temperature of the rapidly radiating lunar surface above the freezing-point.

In a note appended to Mr. Lockyer's translation of M. Guillemin's work on "The Heavens," the Rev. T. W. Webb thus corrects the author's rather positive statements concerning the total absence of a lunar atmosphere: "After all fair deductions on the score of imperfection of observation or precipitancy of inference, there are still residuary phenomena, such as, for instance, the extraordinary profusion of brilliant points which on rare occasions diversify the Mare Crisium, so difficult of interpretation, that we may judge it wisest to avoid too positive an opinion." Now the Mare Crisium is a great depression of the lunar surface close upon that edge of the moon which, to our vision, first receives and loses the solar illumination. If I am right, aqueous vapour should be suddenly forming there during the early crescent period after the new moon, and the hoar-frost should be as suddenly precipitated as this wide depression rolls towards the darkness after the full moon. In that chapter of the "Fuel of the Sun" which is devoted to the meteorology of the moon and Mercury, I have discussed some of the theoretical results of these conditions and the appearances they should present. I may here merely add that, as the temperature of any part of the moon's unmantled surface must directly and very rapidly vary with the incidence of solar radiation, all the undulating regions of the moon must at morning and evening have a very patchy temperature, the slopes towards the sun being hotter than our tropics, while the opposite side of the same hill receiving the solar rays with great obliquity, and radiating into space almost without impediment, must retain a freezing temperature, and thus the cryophorous phenomena, which Sir John Herschel describes as a possible result of the contrasted temperatures of the opposite sides of the moon, should be effected even by the shady lunar craters and contrasted hill-slopes.

On the highlands of the moon no appreciable amount of hoar-frost precipitation should take place on account of the absence of sufficient atmosphere; but on the deeper maria, wherever the conditions are the most favourable, the patchy temperature should produce patches of such precipitation. If anywhere visible, these should be seen on the Mare Crisium, on account of its proximity to the edge of the moon, for there the morning rays that strike most obliquely upon the cold slopes would be the most effectively reflected towards the earth. Not

having seen any original or detailed account of the phenomena to which Mr. Webb alludes, I am unable to say whether they fulfil these theoretical conditions, but I believe that something more may be learned by means of careful observations specially directed to the elucidation of the questions I have suggested.

W. MATTIEU WILLIAMS

Woodside, Croydon, Oct. 23

Pendulum Autographs

It may interest some of your readers to know that they can for themselves observe in the most accurate manner the motion of the compound pendulum described by Mr H. Airy* by merely attaching the ends of a fine thread to two points in the ceiling of a room, and suspending a leaden bullet by means of a second thread tied to the middle point of the former, so that the bullet may just escape the floor. Lay underneath a large sheet of white paper ruled with two dark lines at right angles to each other to correspond to the two axes of vibration. It is Mr. Airy's experiment with the hoop on an extended scale. The motion of the bullet, unimpeded by contact of pencil with paper, is graceful and accurate in the extreme.

Perhaps the most remarkable case is that in which the two points of suspension are taken about an inch apart, and the third about half an inch below them; the pendulum will now keep reversing its motion as uniformly as before, and apparently without any adequate cause, a matter of astonishment to the uninitiated spectator.

I believe the general equation to the path, including all the curves described, will be found to be $\sqrt{n \cos^{-1} \frac{x}{a}} = \sqrt{m \cos^{-1} \frac{y}{b}}$, where the particle starts from the point (a, b) and is attracted to the axes of X and Y by forces = $-ny$ and $-mx$ respectively.

Woolwich, Oct. 24

GEO. S. CARR

Exogenous Structures in Coal Plants

I CORRIALLY agree with your recommendation that discussion on the EXOGENOUS Stems of the Coal Measures should cease for the present. It is evident that I shall not convince my two opponents, and they are as far as ever they were from convincing me. But I must request that in justice to me, you will allow me to enter a protest against the last paragraph of Prof. Dyer's article, in which he objects to my applying the term Protoplasmic to the cambium layer, and endeavours to show that I am two hundred years behind the age in my physiology. I cannot but think that Prof. Dyer, when he penned that paragraph, knew perfectly well in what sense I used that expression. I meant by it nothing more than is implied in the following sentence, taken from Prof. Balfour's "Manual of Botany," p. 43, which certainly does not belong to the age of Grew:—

"External to the woody layers, and between them and the bark, there is a layer of mucilaginous semifluid matter, which is particularly copious in spring, and to which the name Cambium has been given. In this are afterwards found cells, called Cambium Cells, of a delicate texture, in which the protoplasm and primary utricle are conspicuous."

Classification of Fruits

It seems from the numerous attempts that have been made that a philosophical classification of fruits is either unattainable or practically of very little value when attained. At any rate working botanists have, as a rule, discarded the majority of the carpological terms that are to be found in text-books as too cumbersome or too uncertain in their application. Among the latest attempts at simplification in the matter of the classification of fruits are those of my friends Prof. Dickson and Dr. M'Nab (see NATURE, vol. iv. p. 475). Both of these are open to some criticism on matters of detail, but I can hardly expect you to accord me space to point out what I believe to be the merits or shortcomings of their respective schemes. I should also trespass too much on your courtesy and on the patience of your readers did I enter into any engthened explanation of the following scheme, in which I have adopted to some extent the nomenclature of Prof. Dickson

and Dr. M'Nab, and which I offer for consideration solely on the grounds of expediency and simplicity:—

Classification of Monothalamic Fruits

- | | |
|---|------------------------------------|
| A. Ripe pericarp uniform | I. Nuts or Achenocarpis. |
| Fruits indehiscent | II. Pods or Regmacarps. |
| Fruits deliscent | |
| B. Ripe pericarp of two or more layers of different substance * | III. Stone-fruits or Pyrenocarpis. |
| Seeds within a hardened endocarp | |
| Seeds embedded in pulp* | IV. Berries or Sarcocarps. |

I. Nuts or Achenocarpis

WINGLESS—

- | | |
|---|-----------------------|
| Fruit of one carpel, or, if of more, apocarpous | Achene |
| Fruit of more than one carpel | |
| Carpels ultimately separate but indehiscent | Carceral (Cremocarp). |
| Carpels inseparate | |
| Pericarp adherent to the seed . . . | Caryopsis. |
| Pericarp free from the seed, within a cupule | Glans. |
| WINGED | Samara |

II. Pods or Regmacarps

- | | |
|-----------------------------------|---|
| Fruit of one carpel | |
| Opening by one suture | Follicle |
| two sutures | Legume |
| transversely | Lomentum (Dichisma, M'Nab) |
| Fruit of more than one carpel | |
| Opening by pores or sutures . . . | Capsule (Siliqua) (Regma) (Conceptaculum) (Tryma, &c.). |
| Opening transversely | Pyxis. |

III. Stone-fruits or Pyrenocarpis

- | | |
|--|--|
| Carpels one or more, superior . . . | Drupe (Fibro-drupe as in Cocos, Grewia, sp., &c.). |
| Carpels one or more, adherent to, or enclosed within a fleshy receptacle . . | Pome (Sphalerocarpium, as in Hippohad). |

IV. Berries or Sarcocarps

- | | |
|----------------------------------|-----------------------------------|
| Seeds embedded in pulp | Bacca (Hesperidium) (Uva) (Pepo). |
|----------------------------------|-----------------------------------|

I believe that the foregoing arrangement will include most of the varieties of fruits and seed-vessels, though, as in all similar cases, exceptional forms are not readily sorted into their proper place; the fruit of such Cassias as *C. Fistula*, generally called a lomentum, is a case in point. For general purposes the varieties enclosed in brackets may well be omitted, save in the case of so well known and constantly used a term as *siliqua*, which, despite Prof. Dickson's veto, I think is too useful practically to be lightly abandoned.

MAXWELL T. MASTERS

The Berthon Dynamometer

ABSENCE from home, and many engagements, have prevented an earlier reply to "W. R.'s" letter in NATURE, October 5. In my previous communication I believe I gave the address of the inventor, to whom I thought reference might naturally be made; in order, however, to meet "W. R.'s" wish, I will explain the construction of the very simple but efficient instrument in question. It is merely a V gauge, formed of two pieces of thin brass converging at a very acute angle, and graduated along one of the edges; the divisions being viewed through a lens held in the

* The pericarp is here understood as including not only the ripened carpellary wall, but also any adjunct to it which in process of development may be combined with it. In the same manner the pulp may be a production from the carpel or from the seed itself.

hand simultaneously with the image of the object-glass or speculum formed by the eye-piece; the diameter of that image is given at once by the divisions to $\frac{1}{10}$ of an inch, and can be readily estimated to half that value. The arrangement mentioned by "W. R." is no doubt very convenient, and quite adequate for his purpose; but for high powers I should suppose that the comparative coarseness of the engraved lines would make itself much more felt than it is in Mr. Berthou's invention, and the balance of economy is so greatly in favour of the latter in comparison with every contrivance with which I am acquainted, that I have no hesitation in saying that it ought to be in the hands of every amateur who cares to know the magnifying power of his telescope. It may be procured for five shillings, of Mr. Tuck, watchmaker, Romsey.

T. W. WEBB

New Form of Cloud

THE kind of cloud described by M. André Poëy (NATURE, Oct. 19, 1871, p. 489) is by no means new or rare if I can judge correctly from the figure and explanation. It may often be seen on the lower part of the flank of a great rain or thunder cloud, and appears to arise from the dropping or subsidence of portions of the air heavily loaded with watery particles. My own impression is that it appears when the cloud is about to break up. M. Poëy will find the cloud described in the *Philosophical Magazine* for July 1857, where the name of *droplets* is given to the form, and its position in a thunder cloud indicated by a figure. J.

Spectrum of Blood

IN my letter, published in the last number of NATURE, I am strangely enough made to say that "we must not rely on the spectrum." This is an error of the printer. The sentence should have been:—"I have always argued that in such inquiries we must not rely on *one* spectrum, but compare the action of various reagents." H. C. SORBY

Broomfield, Sheffield, Oct. 28

Earthquake in Burmah

I HAVE not read in your "Notes" any record of the earthquake which was felt at daylight of the 16th February last in this city, in two successive and gentle but decided shocks, doing no damage, but which, from the files of the Calcutta *Englishman* of February 18, seems to have been severe to the N.W. of this, extending through Cachar, Silchar, Gowahatty, to Calcutta and Barrackpore.

This earthquake, you will observe, is synchronous with those of the western hemisphere already recorded by you.

CHARLES HALSTED

Mandalay, Burmah, Sept. 1

A Plane's Aspect

I AGREE with Mr. Proctor that the disuse of the term "position" in geometry would be a serious misfortune; happily, however, it is not its disuse, but the prevention of its misuse which is contemplated. I cannot agree with him that "position" is a word "which no one can misunderstand," for his own letter is a striking example of its being misunderstood, either by Mr. Proctor, or by others. "Aspect and slope," he tells us, "indicate two elements, which, together, fix the position" of a plane. Geometers, however, certainly understand, when a plane is said to be given *in position*, that something more than its aspect and slope may be regarded as known. Parallel planes have necessarily the same slope and aspect, but surely not the same position. To be told that, because its slope and aspect are invariable, the plane of Saturn's rings has a fixed position in space, notwithstanding that the planet moves bodily in its orbit, would scarcely satisfy a student of astronomy accustomed to geometrical precision.

There can be no doubt that "position" is the true English equivalent of the German word "Lage," and that no ambiguity of the kind above indicated could attach itself to the term, had we a suitable English rendering for the word "Stellung." I do not consider the term "aspect" to be perfect as an equivalent for "Stellung," but I have no hesitation in admitting that Mr. Laughton's suggestion is happier than any previous one I can remember. Mr. Proctor declares his intention of opposing the

"use of the word 'aspect' in a sense not at present assigned nor properly assignable;" but when he wrote thus, he had not seen the letter of Mr. Wilson wherein the term "aspect" is very rigidly defined to be the direction of the normal. To me this very facility with which the word "aspect" lends itself to rigid definition, is a ground of objection against it. I have never seen Stellung defined in the manner in which Mr. Wilson has defined "aspect." Von Staudt, in whose admirable writings I first met the word, introduced it thus: "Parallel planes possess something in common, which may be regarded as appertaining to each one of them, and shall be called their 'Stellung'; the 'Stellung' of a plane, therefore, is determined by any plane which is parallel thereto, and two planes have the same 'Stellung' or different 'Stellungen' according as they are parallel to, or intersect one another."

That the term "aspect" is not sufficiently elastic to permit of its taking the place of "Stellung" in the above passage cannot, I think, be well maintained by Mr. Proctor, seeing that he has not himself hesitated to use it in two widely different senses in the following passage of his letter: "I can see no reason why 'aspect' should be regarded in a new and unfamiliar aspect." The expression "aspect of a plane," whether it be retained or not as the equivalent of the "Stellung einer Ebene," appears to me, I confess, to be much too good to be claimed by Mr. Proctor as indicative solely of the direction of the projection of the normal upon a certain plane of reference. I would suggest, in the interest of his twelve excellent books, that he might qualify "aspect," as thus defined, by an appropriate adjective, for the term is there used in a very technical sense indeed, and is not even applicable to all planes. Although Mr. Proctor can assign, for example, a southerly aspect to the face of a roof which has a slope of 30°, he would find some difficulty in describing the aspect of a roof which has no slope at all, whereas Mr. Wilson would without hesitation pronounce its aspect to be vertical.

Athenæum Club, Oct. 31

T. ARCHER HIRST

IT is due to my friend and your correspondent, Mr. Cecil J. Monro, of Hadley, to state that, to my knowledge, he was in the habit of employing the word "aspect" in this technical sense long before the publication of Mr. Laughton's letter, and I should not be surprised to learn that other geometers have used it before Mr. Monro.

I think Mr. Proctor will find few to agree with him in his condemnation of the word so used. For myself I heartily agree with Mr. Wilson in the welcome he accords to this "old friend with a new face."

C. M. INGLEBY

Highgate, N., Oct. 27

I AM glad to find, by Mr. Wilson's letter in NATURE for October 26, that the word "aspect," which I suggested, is accepted by him as satisfactory; as, in fact, the word wanted. But another correspondent in the same number, Mr. Proctor, pertinaciously insists on the superior merit of the word "position," to be used in the particular sense explained by Mr. Wilson in his former letter. In this I conceive Mr. Proctor is entirely wrong.

"In geometrical language"—I quote from Gregory's "Solid Geometry," 1845—"the position of a plane is determined by making it pass through three given points." Mr. Proctor says he "can see no reason why 'position' should be dismissed from the position it has so long occupied." No more can I. I would only call his attention to the fact that the meaning which he would assign to the word "position" is quite different from that which has been accepted, in a technical sense, by geometers, and in an everyday sense by everyday people.

Mr. Proctor's special objections to the word "aspect," rest, it seems to me, on a misconception of its meaning and familiar use. We speak of the aspect of a wall, but not of the aspect of a roof, nor of a hill. What the usage amongst builders in respect of roofs may be, I don't know, but geographers almost invariably speak of the "slope" of a hill, as, for instance, the southern slope of the Himalayas. Put into exact language, the aspect of a plane is the direction of its normal; and as parallel planes have parallel normals, any number of parallel planes have the same aspect, without reference to their position; but no two planes, parallel or not, can possibly have the same position.

The word "slope" is almost equally inadmissible; in the first place, it refers to some other plane, which is apt to cause

confusion; and in the second, although all parallel planes have the same slope, any number of other planes not parallel can also have it; the word is therefore not sufficiently definite. "Tilt," a word spoken of by Mr. Proctor, as though it had been suggested, has no geometrical meaning whatever. As a substantive it is a "tent," or "awning;" it has also been sometimes used poetically as an equivalent to "tournament," and is, I believe, the familiar abbreviation of "tilt-hammer." These are its only meanings, and none of them apply to a plane.

I would only add that I do not quite see what the fact mentioned by Mr. Proctor, that he has written twelve books in the last six years—interesting as it may be from a bibliographical point of view—has to do with the matter.

Oct. 29

J. K. LAUGHTON

THREE elements are necessary to fix the position of a plane as I understand the word "position." If "aspect" and "slope" be the names of two of these, the third will be the perpendicular upon the plane from some fixed point. It is because the term "position" implies the fixedness of this third element that it is inappropriate to express my friend Mr. Wilson's meaning.

My friend Mr. Proctor will pardon me if I do not consider the question entirely settled by the fact that he has written perspicuously and explained clearly by the use of a term which fixes too much. With an improved scientific terminology, he will be able to make his next twelve books superior (if that be possible) to those he has written within the last six years.

"Aspect" and "slope" stand on the same footing, one connotes a reference to the points of the compass, the other to the horizon. Neither can be used in Mr. Wilson's sense without departing from their colloquial meaning, but it is perfectly competent for geometers to take a word from common conversation and give it a scientific meaning. Either of these words may be used in Mr. Wilson's test sentences. Parallel planes have the same slope, two slopes determine a direction, &c.

It is yet possible that some correspondent can suggest a better term, either one imported from ordinary life or one conceived for the purpose.

THE CORRESPONDENT WHO SUGGESTED "SLOPE"

Geometry at the Universities

PROF. THISELTON DYER has well pointed out a distinction which exists between the mathematical courses at Oxford and Cambridge. But his conclusion, that at Oxford "special attention to geometrical methods would pay very well," though acceptable in its way, falls far short of what I advocate. The great want at both Universities is a course of geometrical studies; and the proof that such a want exists is to be found in the fact that the geometrical treatises in use at either University, cover so very limited a range. There are not even any text-books on the geometry of the sphere, cone, cylinder, and like simple solids, or on such curves as the lemniscate, cycloid, and the simpler spirals. A few stray notes on these subjects may be found in some of the text-books, but not a thorough and systematic geometrical investigation of any of them. Geometrical treatises might with advantage range much further. A geometrical treatise on ellipsoids would be of immense use apart from its employment as a means of mental training. Geometrical treatises on paraboloids of both kinds, on hyperboloids of one sheet and of two sheets, on the various orders of ring-surfaces and screw-surfaces, and on many other tridimensional matters, would afford invaluable exercise to the student, besides having a real value to the scientific worker. I venture to express my conviction, that a course of such studies would tend to develop mathematical powers much more thoroughly even than the study of covariants and contravariants, Jacobians, Hessians, *à hoc genus omne*.

If there is one department of mathematical research in which our countrymen are fitted by their mental habits to distinguish themselves pre-eminently, it is precisely this neglected department of geometrical research. As it is, though we have geometers of great power, no systematic geometrical work is done in England. Our treatises range only over the most elementary geometrical subjects, and even in discussing these subjects our writers are fain to accept the assistance of Continental geometers. One would conceive that each of our Universities might yearly send out many who could treat of the elements of geometry without keeping a hand always on some French or German text-book.

Brighton, Oct. 27

RICHD. A. PROCTOR

DEEP-SEA DREDGING IN THE GULF OF ST. LAWRENCE

THE marine zoology of the deeper parts of the River and Gulf of the St. Lawrence has not been investigated until quite recently. This summer, under the auspices of the Natural History Society of Montreal, and in consequence of the kindness of the Hon. Peter Mitchell, Minister of Marine and Fisheries for the Dominion (who not only gave me facilities for dredging on board Government vessels, but also caused sufficient rope to be provided for the purpose), depths of from 50 to 250 fathoms were successfully examined. The greatest depth in the Gulf, to the west of the Island of Newfoundland, as given in the Admiralty charts, is 313 fathoms. It is thought that a general sketch of the results obtained may be of interest to the readers of NATURE.

The cruise lasted five weeks, the first three of which were spent on board the Government schooner *La Canadienne*, and the remaining two on the *Stella Maris*. The area examined includes an entire circuit round the Island of Anticosti, and extends from Point des Monts (on the north shore of the St. Lawrence) to a spot about half way between the east end of Anticosti and the Bird Rocks. As these investigations were almost necessarily subordinate to the special duties on which the schooners were engaged, in several cases the same ground was gone over twice.

The bottom at great depths generally consists of a tough clayey mud, the surface of which is occasionally dotted with large stones. So far as I could judge, using an ordinary thermometer, the average temperature of this mud was about 37° to 38° Fahrenheit, at least on the north shore. In the deepest parts of the river, on the south shore, between Anticosti and part of the Gaspé Peninsula, the thermometer registered a few degrees higher. Sand dredged on the north shore in 25 fathoms also made the mercury sink to 37° or 38°.

Many interesting Foraminifera and Sponges were obtained, but as yet only a few of these have been examined with any care. A number of Pennatulæ were dredged south of Anticosti; the genus has not been previously recorded, so far as I am aware, as inhabiting the Atlantic coast of America. They were found in mud, at depths of 160 and 200 fathoms, and it seems probable that this species, at least, is sedentary, and that it lives with a portion of the base of the stem rooted in the soft mud. *Aetinia dianthus* and *Tealia crassicornis* were frequent in 200 to 250 fathoms. The Echinoderms characteristic of the greater depths are a *Spatangus* (specifically distinct from the common British species), *Ctenodiscus crispatus*, *Ophioglypha Savii* (very large), *Ophiacantha spinulosa*, and *Amphiuva Holboellii*. Marine worms, of many genera and species, were both numerous and fine. Among the more interesting of the Crustacea were *Nymphon grossipes* (?) and a species of *Pycnogonum*. Several of the last named Crustaceans were taken at a depth of 250 fathoms, entangled on a swab, fastened in front of a deep-sea lead, which was attached to the rope, a few feet from the mouth of the dredge. This circumstance tends to show that the genus is not always parasitic in its habits. The Decapods, Amphipods, &c., at least those of greatest interest, have not yet been identified. Among the most noticeable of the marine Polyzoa are *Defrancia truncata*, and what appears to be a *Retepora*. Not many species in this group were obtained in very deep water, and those procured were, for the most part, of small size. About six species of Tunicates were collected. Being anxious to have Mr. J. Gwyn Jeffreys' opinion upon the various species of Mollusca during his visit to Montreal, I studied these carefully first, and submitted the whole of them to him for examination. Twenty-four species of Testaceans Mollusca were obtained at depths of from 90 to 250 fathoms. Nearly all of these are Arctic forms, and eleven of them are new to the continent of America.

The following are some of the most interesting of

the deep-water Lamellibranchiata:—*Pecten granlandicus* of Chemnitz, but not of Sowerby; * *Arca pectunculoides* Scacchi; *Yoldia lucida* Loven; *Y. frigida** Torell; *Neera arctica** Sars; *N. obesa** Loven. Among the novelties in the Gasteropoda of the same zone are the subjoined:—*Dentalium abyssorum* Sars; *Siphonodentalium vitreum* Sars; *Eulina stenostoma* Jeffreys; *Bela Trevelyanii** *Chrysodomus (Sipho) Sarsii**. Three Brachiopods occur in the Gulf, of which *Rhynchonella psilthacea* and *Terebratella Spitzbergensis* are found in about 20–50 fathoms, and *Terebratula septentrionalis* in from 100–250. A few rare shells were obtained in comparatively shallow water; among them an undescribed *Tellina* (of the section *Macoma*), a new *Ostomia*, and *Chrysodomus (Sipho) Spitzbergensis** Reeve. Nor were even the Vertebrata unrepresented; from a depth of 96 fathoms off Trinity Bay, a young living example of the Norway "Haddock" (*Sebastes Norvegicus*) was brought up in the dredge. And off Charleton Point, Anticosti, in 112 fathoms, on a stony bottom, two small fishes were also taken; one, a juvenile wolf-fish (*Anarrhicas lupus*) the other a small gurnard, a species of *Agonus*, probably *A. hexagonus* Schneid.

The similarity of the deep-sea fauna of the St. Lawrence to that of the quaternary deposits of Norway, as described by the late Dr. Sars, is somewhat noticeable. *Pennatulæ*, *Ophiura Sarsii*, *Ctenodiscus crispatus*, several Mollusca, &c., are common to both; but on the other hand, the absence of so many characteristic European invertebrates on the American side of the Atlantic should be taken into consideration. The resemblance between the recent fauna of the deeper parts of the St. Lawrence, and that of the Post-pliocene deposits of Canada, does not seem very close, but our knowledge of each is so limited that any generalisations would be premature.

J. F. WHITEAVES

THE REDE LECTURE AT CAMBRIDGE

ONE of the indirect results of university reform has been the establishing at Cambridge of the Rede Lecture, one of the highest intellectual treats of the whole year, as will at once be acknowledged when the names of the distinguished persons who have delivered it since its establishment in 1858 are known—viz., Professors Owen, Phillips, Max Müller, Willis, Ansted, Airy, Tyndall, Miller, Ruskin, Huggins, General Sabine, Sir W. Thomson, and Mr. Norman Lockyer. For many years past there had been certain lecturers at various colleges, whose duty it was to deliver lectures on mathematics, philosophy, rhetoric, and logic; but in 1858 the endowments for these lectures (originally given in 1524 by Sir Robert Rede, Chief Justice of the Common Pleas in the reign of Henry VII.) were amalgamated, and the result has been the delivery once a year of the Rede Lecture by some distinguished man of science chosen by the Vice-Chancellor for the time being. Such is the history of the benefaction; but it must now be added that as the remains of this distinguished man lie in a village church in Kent, that of Chiddingstone, near Eden Bridge, in which parish he lived and died, without a memorial or inscription of any kind over his grave, it is proposed to do for him what Cicero did for the unhonoured grave of Archimedes, and an effort is, therefore, being made to mark his place of burial by erecting a window of stained glass in the chancel that he built. The cost of the memorial, with suitable inscription, cannot be less than 160*l.*, but nearly 70*l.* has been raised by subscriptions from the distinguished persons who have delivered the lecture, and by other friends, members of the university and otherwise—viz., the Earls of Powis, Derby, and

* I am indebted to Mr. Jeffreys for the identification of species to which an asterisk is attached. He corroborates also my determination of the remainder.

Strathmore, the Vice-Chancellor, the Masters of Jesus and Clare Colleges, the Provost of King's, Professors Selwyn and Sedgwick, Mr. Beresford-Hope, M.P., Sir John Lubbock, M.P., the Public Librarian, Rev. W. H. Latham, and J. Brocklebank, with many others; but the amount thus subscribed, together with the local effort, is inadequate for the full completion of the memorial, and it is hoped that there will be some others who will be willing to help on the work. Mr. Norman Lockyer, F.R.S., the present holder of the office of Rede Lecturer, has kindly consented to receive subscriptions at 6, Old Palace Yard, Westminster.

It is proposed to erect the following inscription, from the pen of Professor Selwyn, who will receive any subscription forwarded to him at Cambridge.

THE CONJOINT EXAMINATION SCHEME*

THE proposition carried at the last meeting of the Council of the College of Surgeons clears away, we suppose, the last difficulty in the way of an amalgamation between the Colleges of Physicians and Surgeons for the purposes of examination and of issuing diplomas. It is remarkable that the College of Surgeons should have come back to the original proposal, though it was at first demurred to and given to a committee for consideration. The College of Physicians, at its Comitia on Thursday, finally agreed to this proposal; and it now only remains for the General Medical Council to give its consent under the Medical Act of 1858, so as to allow of the fusion in question.

In order to get at the practical working of the proposed scheme of division of fees, we may take the present income of the College of Surgeons from the membership diploma, adding 10*l.* for each diploma issued to represent the additional fee to include the College of Physicians. The sum produced by the membership diploma during the last financial year was close upon 8,000*l.*; and if we add 10*l.* for each of the 291 diplomas issued, we have in round numbers the sum of 11,000*l.* The proposed scheme is, that one-half of this should be devoted to all the expenses of the examinations, and that the remaining moiety of 55,000*l.* should be divided into thirds. One-third is to go to the support of the Museum of the College of Surgeons and its unendowed professorships, one-third for the maintenance of the personnel of the College of Physicians, and one-third similarly to that of the College of Surgeons. This will give the Hunterian Museum and each of the Colleges some 1,800*l.* a year apiece, irrespective of other sources of income. With this income, it will, we imagine, be perfectly possible to carry on satisfactorily the establishments in Pall Mall and Lincoln's Inn Fields, if due economy be observed and proper supervision exercised over the subordinate officials. The Hunterian Museum will be upon a somewhat shorter allowance than heretofore; but if this prove insufficient, Parliament must be appealed to for a grant in favour of what the Council of the College of Surgeons properly characterises as an "institution of national as well as professional importance."

* Reprinted from *The Lancet*.

SIR RODERICK MURCHISON

THE life of a scientific man is for the most part uneventful, and perhaps to the world at large uninteresting. That he was born, lived a certain number of years, and died, are often the chief facts chronicled of the man himself. Of his work and of the influence of his work men are willing to read, but for the story of his life, with its quiet everyday monotony, they care little. Yet it is true, at least of the higher type of mind, that the story of the man's life and the history of the work he accomplished are inseparably connected, and are each necessary for the understanding of the other. There arise, too, ever and anon instances when the man was not merely a man of science, but one whose scientific career formed as it were a nucleus round which many other and often divergent interests gathered. Such a man's life is sometimes

linked in so many ways with that of the society in which he lived, that its chronicle becomes in some degree the history of his time. And such a man was Roderick Impey Murchison. By no means standing on the highest platform of scientific intellect, a patient gatherer of facts rather than a brilliant generaliser from them, he yet gained by common consent in the commonwealth of science the position of a king, under whom men of all ranks, and even men of far higher ability and attainment than his own, were not only willing but delighted to serve. He held a place which no other man of science left among us now fills. It was not merely his achievements in geology, memorable as these were, which gave him that proud pre-eminence, nor did he owe anything to success in other branches of science, for he seldom travelled beyond what he knew to be his proper domain, nor to graces of literary style, on which men of slender acquirements often float

THE LATE SIR RODERICK I. MURCHISON

into popularity. He wrote only on geological and geographical subjects, and in a solid matter-of-fact way not likely to attract readers who did not previously care for his subjects. It was his personal character, his noble-heartedness, his indomitable energy, his tact and courtesy, the dignity and grace which he never failed to show even to opponents, and the social position which his family and fortune gave him, and which enabled him greatly to extend the respect shown in society to science and scientific men,—it was these causes which largely went to make Sir Roderick's influence what it was. A narrative, to do him justice, should tell how these causes came into play, and how, combined with the regard which he could always claim for his solid contributions to science, they placed him so high in the scientific circle in which he moved.

Murchison was born on February 19, 1792, at his

father's little estate of Tarradale, in Eastern Ross shire. He used to speak with fondness of the fact that he first saw the light amid those old palæozoic sandstones, conglomerates, and schists, on which he was afterwards to rest part of his title to fame. Yet it was not among the wilds of Ross that he acquired a love for rocks. He was removed from his birthplace at an early age, and taken into Dorsetshire, and though when still a child he was brought back into Scotland, and remained with his mother at Edinburgh for a short while, it was in England that he spent most of his boyhood, and where he was educated. At the age of fifteen he obtained a commission in the 36th Regiment of Foot, and served in the Peninsula under Sir Arthur Wellesley. He carried the colours at the Battle of Vimiera, and went through much hardship in the retreat of Corunna. At the end of the war,

after having become a captain of dragoons, he quitted the army, and marrying the daughter of General Hugonin, settled in England. So ended what he used to call the military episode of his life. Next came the fox-hunting period, when his activity of disposition found vent in the excitement of the chase, into which he threw himself heart and soul. He might have continued a merry, hearty, sporting, country gentleman, but for the influence of his wife, who was fond of natural history pursuits, and the advice of Sir Humphrey Davy, who, meeting him at the house of Mr. Morritt, of Rokeby, and seeing in him promise of something better than fox-hunting, advised him to attend the Lectures of the Royal Institution. Sir Roderick used to tell an interesting anecdote of that early beginning of his scientific career. He was attending the lectures of (if we remember) Dr. Brande, when one day the lecturer's place was taken in his absence by a pale thin lad, his assistant, who gave the lecture and experiments in so admirable a manner as to be received at the end with a hearty round of applause. It was Michael Faraday, and this was his first public appearance.

After gaining considerable knowledge from public lectures and private instruction, Sir Roderick's active mind sought as early as possible to study Nature in the field. Geology was the branch of science which suited best a nature so fond of out-of-door life as his. He had made the acquaintance of William Smith, the father of English Geology, from whose own lips he had learned the order of succession which the marvellous patience and ingenuity of that pioneer of the science had made out for the rocks of England and Wales, and indeed, as was afterwards found, for the rocks of all the world. In the year 1825, when he was thirty-three years of age, he wrote his first-published paper, "A Geological Sketch of the North-western Extremity of Sussex and the adjoining parts of Hants and Surrey." From that time onwards for nearly half a century he continued to furnish accounts of his observations in the field. Beginning, as was natural, with the district in which he lived, he soon extended his researches even as far as his own native Highlands, then step by step over the Continent of Europe, even as far as the confines of Asia. He has published more than 100 memoirs on British and Continental Geology, besides numerous addresses to scientific societies, and in addition to upwards of twenty memoirs in conjunction with other authors. To all this mass of work must be added what he published in separate volumes—his great "Silurian System," his splendid volumes on "Russia," and the successive editions of his "Siluria."

Of the incidents of his life during its scientific period it is not necessary here to say much, nor to try to count up the honours showered on him from all parts of the world. There was hardly a scientific Academy anywhere which had not enrolled him among its associates, and to the dignities conferred on him by his own Sovereign, were added others conferred by Emperors and Kings abroad. His time was largely passed in London, where he took an active share in scientific work. But every year he made a tour either in this country or on the Continent, and added to our knowledge of the geological structure of the districts which he visited. Sometimes these tours were prolonged, and in the case of his Russian campaign he was absent for two or three years from England.

At the time when Murchison broke ground as a geologist, the science of geology had entered a new phase of its history. The absurd system of Werner, though still upheld by high authority in this country, was daily losing ground, and the simple and obvious classification of William Smith on the one hand, and the doctrines of Hutton on the other, were guiding all the younger intellects of the day. Murchison's tact is nowhere more conspicuous than in his choice of a field for the exercise

of his patient energy of research. He saw that the old Wernerian notion of "transition" rocks was doomed, and that it would be a task well worthy of his time and toil to unravel the succession of these rocks, and try to introduce into them the same order and consistency which Smith had shown to mark the Secondary series of England. He chose for the scene of his researches the border country of England and Wales, where these old rocks are well displayed, and after five years of unremitting labour he produced his "Silurian System"—a work, which, though dealing only with the rocks of a limited tract of Britain, yet first unfolded the earlier chapters of the history of life upon our globe. The classification he adopted, though of course necessarily subject to local variation and change, has been found to hold true on the great scale over the whole world.

This work laid the foundation of Sir Roderick's fame. In his subsequently published "Siluria," which has gone through several editions, he recast the original work, introducing much detail regarding the extension of Silurian and older palæozoic rocks into other countries; but while in the later publication, the results given were necessarily often the work of other observers—the "Silurian System" remains a monument of the unaided labour of a mind quick in observation, sagacious in inference, patient in the accumulation of data, and full of that instructive appreciation of the value of facts not yet understood, which is near of kin to genius.

It would be beyond the limits of this journal to offer an adequate outline of Sir Roderick's scientific work. He was distinctly and specially a geologist. His early attachment to palæozoic rocks never waned, and though now and then he was led to make and record observations on later formations, he always returned to the older deposits as his natural inheritance and domain. He was not a palæontologist, but no geologist could use more skillfully than he the data furnished by palæontology. This faculty he acquired at the beginning of his career, and it marked all his work in the field both at home and abroad. It enabled him to apply to distant countries the principles which he had so successfully used in his own. Perhaps the leading idea of his scientific life should be regarded as the establishment of the order of succession among rocks. This was what he did in the Silurian region originally, and what he always endeavoured to ascertain in every district to which choice or accident might lead him. He had a singularly quick eye for the geological structure of a country. No one who travelled with him through a hilly tract, and, after listening to his rapid inferences, has gone actually over the ground to see, could fail to be struck with the accuracy with which he seized on some of the leading features, and from these deduced the general arrangement of the rocks. It was in this way, and by the use of palæontological evidence, that he was enabled to arrive at one of the most brilliant generalisations he ever achieved, when he brought order and intelligibility into the chaos of the so-called primary rocks of his own Scottish Highlands—a deduction which is, perhaps, destined to bear fruit of which he never dreamed, in the still obscure subject of metamorphism.

Sir Roderick Murchison's early training in geology was acquired at a time when men believed in periodic cataclysms, by which the surface of the globe was destroyed and renewed. He never could, and he never seemed seriously to try, to shake himself free from the influence of that training. Though he modified his views as years went on, he remained a member, and indeed in this country the leader, of the Cataclysmic School. The upholders of a long line of successive creations and of the former greater intensity of all geological causes have lost in him one of their ablest, staunchest, and most influential associates.

To the world at large, however, it was not from his geological work chiefly that Murchison was known. His

generalisation as to the probable gold-bearing nature of the Australian quartz-country, and as to the probable aspect of the interior of Africa, are probably familiar to most people. But in later years what has especially brought his name into prominence is the chivalrous devotion with which he has maintained one might almost say the national belief in the welfare of Dr. Livingstone. Yet this is only a sample, though one which has come more publicly before us, of the tenacious friendship and active benevolence which have always marked him. As President of the Geographical Society—a society which is in a sense his own creation—he had frequent opportunities of befriending not only the cause of geography but the personal well-being of travellers, and he never failed to use them. The geographers have good cause to lament the death of their chief.

Of the man himself, what he was as he lived and moved among us, his loss is too recent to permit us justly to speak. We can only think of him as the stately courteous old gentleman, carrying even to the last that military bearing which dated from the days of Wellesley and Moore, kindly and thoughtful in his kindness—a man whose friendship, once given, even ingratitude and injustice could not wholly alienate. He was not without some of the littlenesses of humanity, but they were so transparent, and often even so child-like, that we forget them in the recollection of all the goodness of heart and strength of head and nobility of nature which have gladdened us for so long, but which are now only subjects of tender remembrance.

ARCH. GEIKIE

HOMOPLASY AND MIMICRY

ALL students of the remarkable phenomenon of superficial resemblances in the animal and vegetable kingdom will be glad that Prof. Dyer has published an extension of the paper which he read on this subject at the Edinburgh meeting of the British Association. It is especially satisfactory that he has abandoned the very objectionable term "pseudomorphic," and substituted that of "homoplastic," a very much better term, because it simply expresses a fact without committing one to any theory. There are, however, one or two points in his paper of last week, on which I should wish to be allowed to comment.

Prof. Dyer holds that the distinction between "mimicry" in animals and "homoplasy" in plants, is "sufficiently obvious," the difference assigned being, apparently, that in the one case it takes place between species found in the same locality, in the other between species unconnected geographically. I doubt, however, whether facts will warrant this distinction. The most remarkable instances of "mimicry" among animals hitherto published are, undoubtedly, in the case of species inhabiting the same area; but I am inclined to think that, when attention is called to the subject, others will be found between animals not so associated, though these instances would naturally not attract so much observation. And secondly, homoplasy in plants does frequently occur in species occupying the same area. The statement reported to have been made by Prof. Dyer at Edinburgh that "the resembling plants are hardly ever found with those they resemble," would scarcely be borne out by a careful investigation. The real objection to the terms "mimicry" and "imitation" is that they seem to imply a *conscious* effort at convergence, which will hardly be conceded in the case of Lepidoptera any more than of Ferns. The substantial difference between the two is that, in the case of animals, the resemblance appears to be protective, while in the case of plants, there is seemingly no such benefit arising from it; but this is a difference in result and not in the nature of the phenomenon itself. I fail to see that the objections to the use of these terms in the case of

plants do not equally apply to animals; we have no reason to suppose that the two sets of phenomena are not produced by similar causes.

Prof. Dyer states, and no doubt truly, that the external resemblances of plants may frequently be traced to the effect of similar external conditions, and quotes in support Mr. E. R. Lankester's view with regard to animals. But in assuming that this explanation will account for all such phenomena if fully investigated, I think too much is assumed. Cases of homoplasy are referable to two distinct classes—resemblances in general habit, and resemblances of particular organs. The former, as in the case of the homoplasy between a *Cactus* and a *Euphorbia* or a *Stapelia*, or between a *Kleinia* and a *Cotyledon*, are no doubt due to the operation of similar external conditions of climate and soil. But in the second class this explanation wholly fails.

As illustrations of the kind of resemblance I mean, I may refer to the two collections of "mimetic plants" exhibited by Mr. W. W. Saunders at the two last *soirées* of the Linnean Society, a list of which will be found in NATURE for May 26, 1870, and May 4, 1871. The extraordinary resemblance in the markings of the leaves in plants thus grouped together, might well deceive the most experienced botanist. To account for this homoplasy on the ground of similar external conditions, is to start a mere hypothesis, without any facts to warrant it. A still more curious series of resemblances occurs in the case of fruits than of leaves, so close that it has deceived botanists of the experience of the elder Hooker, Bentham, and Kunth into placing species in a genus with which they have no structural affinity whatever. I have in my mind in particular two samaroid fruits, both from the forests of Brazil, so absolutely identical in external facies, that distinction is quite impossible without dissection, and yet belonging to exceedingly remote orders. I will not, however, say more on this point, as it would be impossible to appreciate the closeness of the homoplasy without drawings, which I hope shortly to be able to publish. The singular part of this resemblance is, that, as far as we know, it is never protective. In our Bee-orchis we have what might well have been assumed *primum facie* to be a case of protective resemblance, the flower being so fashioned in order to attract bees to assist in its fertilisation. It is remarkable, however, that the Bee-orchis is one of the few plants that appear to be perpetually self-fertilised, never being visited by insects. It is just possible that we have an instance of protective or rather beneficial resemblance of scent in the case of the carrion-like odour of the flowers of *Stapelia*, which attracts blue-bottle and other flies.

In a paper read at the recent meeting of the American Association for the Advancement of Science, by Prof. E. D. Cope, I find the following thoughtful remarks:—"Intelligence is a conservative principle, and will always direct effort and use into lines which will be beneficial to its possessor. Thus, we have the source of the fittest, *i.e.*, addition of parts by increase, and location of growth-force directed by the will, the will being under the influence of various kinds of compulsory choice in the lower, and intelligent option among higher animals. Thus intelligent choice may be regarded as the originator of the fittest, while natural selection is the tribunal to which all the results of accelerated growth are submitted. This preserves or destroys them, and determines the new points of departure on which accelerated growth shall build."

Biologists generally are, probably, hardly prepared to apply the terms "intelligence" and "will" to the vegetable kingdom; but the use of the term "vegetable life" seems to me to imply of necessity that there are powers at work in the economy of the plant, as of the animal, which it is vain to attempt to reduce to manifestations of the forces which govern the inorganic world.

ALFRED W. BENNETT

NOTES

IN our present number we give a portion of Prof. T. Sterry Hunt's Address at the Indianapolis meeting of the American Association, and propose in following numbers to reprint some of the more important papers read at the meeting. The next meeting will be held at San Francisco, and the following officers were elected for the meeting of 1872: President, Prof. J. Lawrence Smith, of Louisville; Vice-President, Prof. Alex. Winchell, of Ann Arbor; Permanent Secretary, Prof. Joseph Lovering, of Cambridge; General Secretary, Prof. E. S. Morse, of Salem; Treasurer, William S. Vaux, of Philadelphia; Auditing Committee, Dr. H. Wheatland, of Salem, and Prof. H. L. Eustis, of Cambridge; Standing Committee, *Ex Officio*, Messrs. Smith, Winchell, Lovering, Morse, Vaux, Gray, Barker, Putnam. Committee from the Standing Committee to arrange for next meeting, Profs. J. L. Smith, Asa Gray, Joseph Lovering, in connection with a committee from the Association at large, consisting of Profs. J. L. Smith, J. D. Whitney, and O. C. Marsh.

THE Senate of the University of London on Wednesday last week exercised for the first time its privilege, under the Public Schools Act, of appointing a member of the governing body of Rugby and Charterhouse Schools. To Charterhouse it appointed Mr. Busk, F.R.S., President of the Royal College of Surgeons, thus recognising the claims of science in the direction of education. To Rugby it nominated Dr. Temple, Bishop of Exeter (late head master of Rugby).

THE Inaugural Meeting of the Newcastle College of Physical Science on Tuesday last week was a great success. The Council decided unanimously, on the application of upwards of seventy ladies, to make no distinction of sex in the admission of pupils, placing all on a footing of exact equality. The total number of students admitted up to the time of the inaugural ceremonial, was fifty-one. In contrast to this we may note that last week the governing body of the University of Edinburgh rejected by a small majority Dr. Alexander Wood's motion, "That, in the opinion of this Council, the University authorities have, by published resolutions, induced women to commence the study of medicine at the University; that these women, having prosecuted their studies to a certain length, are prevented from completing them for want of adequate provision being made for their instruction; that this Council, without again producing any opinion on the advisability of women studying medicine, do represent to the University Court, that, after what the Senatus and Court have already done, they are at least bound in honour and justice to render it possible for those women who have already commenced their studies to complete them."

ACCORDING to M. Le Verrier, Prof. Alluard of Clermont-Ferrand has obtained a grant of the necessary funds for establishing his long-projected observatory on the summit of the Puy-de-Dôme.

FATHERS Secchi and Denza and M. Diamilla Müller are engaged in organising a series of researches in the Mont Cenis tunnel, for the purpose of ascertaining what variations gravity and magnetism may undergo there.

THE Mayor and other inhabitants of the town of Belfast lately expressed their sense of Prof. Wyville Thomson's many efforts for the encouragement of Science, and for the improvement and gratification of the working classes, in a suitable address, accompanied by a valuable service of plate.

THE *Bulletin Astronomique* gives the following observations of Tuttle's comet. From M. Borrelly of Marseilles:—October 12, Marseilles M.T., 16^h 29^m 19^s, R.A. 9^h 9^m 44^s 68, Decl. + 44° 16' 15". The comet had the appearance of a diffuse nebulosity

badly defined; it appeared elongated in the direction N.W. by S.E.; it was feeble but of moderate extent, about 2' 20". The approximate correction of Mr. Hind's ephemeris, given by this first observation, is $\Delta \alpha = + 0^m 5^s$, $\Delta \delta = + 1^{\circ} 3'$. From MM. Loewy and Tisserand of Paris:—October 14, Paris M.T. 12^h 36^m 12^s 2, R.A. 9^h 14^m 35^s 29, polar distance, 47° 12' 13". The comet resembled a whitish nebulosity, diffuse, and of irregular form. Its diameter was about 3'; the light scarcely that of a star of the 13th magnitude.

DR. HOOKER, of New, has placed the Lichens which he collected during his Morocco expedition in the hands of the Rev. W. A. Leighton, of Shrewsbury, for examination and determination.

THE first Servian Agricultural Exhibition was opened with great ceremony at Belgrade, on October 2.

IN addition to the announcements last week, the following works are in preparation:—From Edward Stanford:—The Laws of the Winds Prevailing in Western Europe, by W. Clement Ley, with charts, diagrams, &c., Part I.; Notes on the Geography of North America, Physical and Political, intended to serve as a text-book for the use of elementary classes; Notes on the Geography of South America, intended to serve as a text-book for the use of elementary classes. The following additional volumes are also announced to Weale's Series, published by Lockwood and Co.:—Analytical Geometry and Conic Sections, by J. Hann, new edition, entirely re-written by J. R. Young, numerous diagrams; Treatise on the Construction of Iron Bridges, Girders, Roofs, and other Structures, by Francis Camplin, C.E., numerous illustrations; Drawing and Measuring Instruments, by J. F. Heather, M.A., numerous woodcuts; Optical Instruments, by J. F. Heather, M.A., numerous woodcuts; Surveying and Astronomical Instruments, by J. F. Heather, M.A., numerous woodcuts; Physical Geology, partly based on Portlock's "Rudiments of Geology," by Ralph Tate, numerous woodcuts; Historical Geology, partly based on Portlock's "Rudiments of Geology," by Ralph Tate; Emigrants' Guide to Tasmania and New Zealand, by James Baird, B.A.; Workman's Manual of Engineering Drawing, by J. Maxton, seven plates and nearly 325 woodcuts; Mining Tools, for the Use of Mine Managers, Agents, Students, &c., by W. Morgans; Atlas to the above, containing 235 illustrations.

A NEW horticultural Magazine is announced to be shortly commenced, with the title of *The Garden*, under the editorship of Mr. W. Robinson, F.L.S., author of "Hardy Flowers," "Alpine Flowers for English Gardens," &c.

A COMPLETE geological and statistical history of Australia by C. E. Meinicke, with a magnificent coloured map by A. Petermann, appears as a supplementary number of Petermann's "Mittheilungen."

THE Ven. Archdeacon Pratt has reprinted a lecture on "The Descent of Man in Connection with the Hypothesis of Development," delivered at the Dalhousie Institute, Calcutta, on July 28, in which the Darwinian doctrine of evolution is vigorously combated.

THE High Wycombe Natural History Society has resolved upon a new course of action suggested by the fact that its meetings had become pleasant social gatherings rather than in any way furthering the pursuit of natural science. In future the meetings will be held at the house of the President, the Rev. T. H. Browne, F.G.S., and will partake more of the nature of classes for the study of certain subjects. A loss in the number of members is expected, but it is hoped that those who remain will benefit by the change. Other local societies would do well to adopt a somewhat similar arrangement. The Quarterly Magazine of the above body is discontinued.

ASSISTANT-SURGEON VERCHERE, of the Indian Army, has suggested, says the *Medical Times and Gazette*, that some experiments should be made with reference to meteorological influences on sickness and health. Medical Meteorology in India is still all but an unknown science, and, as at present studied, is useless to medical practitioners. The long range of "readings" tells us nothing; but a register of the effects of meteorological conditions on the men selected for the purpose, with all conditions of exposure, &c., taken into account, and compared with the average sickness of a corps for the same period, would teach us more in a few months than yards of meteorological tables. We understand that the Sanitary Commissioners of India are favourable to the proposal of Mr. Verchere, and it will therefore, probably, be carried out.

THE *Wigtonshire Free Press* says that the foundation of a lake dwelling has been discovered by Mr. Charles Dalrymple, Kinellar Lodge, Aberdeenshire, on a small circular island at the south end of the Black Loch, Castle-Kennedy. On removing the surface soil, a circle of stones was discovered, the diameter of which was between 50 and 60 feet. On digging deeper through the stratum of forced earth and stones, three feet thick, what appeared to be a different and older layer of soil was reached. Among this black earth were found wood ashes, bits of calcined bones, and flat stones placed contiguously. Immediately below the stones, at the depth of a few inches, an artificial flooring was discovered, formed of the trunks of oak and alder trees. At this point the level of the loch was reached, and the influx of water prevented further excavations in a downward direction. In 1865-6, by the draining of Dowalton Loch, in the same county, several lake-dwellings were exposed; in the spring of this year, when the White Loch of Castle-Kennedy, which is now in connection with the Black Loch by a short canal, was being dragged with a net for trout, the net brought up a canoe of ancient make. In all likelihood it was the ferry-boat, or one of several perhaps, used by the lake-dwellers.

THERE is a volcanic eruption going on in the Hawaiian Islands at Maunaloa, but its exact site has not been recognised. From Koma the lava was seen at night to rise to a height of several hundred feet in a column. The eruption is supposed to be near the locality of that of 1868, while others think it is nearer the summit of the mountain, on the scene of the great eruption of 1859. On September 6, an eruption took place on the southern slope of Maunaloa.

THE Constantinople earthquake is now known to have originated in the southern region of the island of Scio, where it began strongly, growing weaker towards its northern circumference. At the Dardanelles it was much sharper than at Rodosto, while at Boegas, on the Black Sea, it was very slight, and further on at Varna was not felt.

ANOTHER small place to be marked soon as a big one is Chinboto on the coast of Peru. Its harbour, the finest in the South Pacific, can shelter the navies of the world. It was a great town in the times of the Incas, as remains of a colossal aqueduct will show. Near it are coal mines. It has been abandoned and neglected on account of the difficulties of access, but a railway is now to be constructed to the fertile interior at a cost of 6,400,000*l*.

TO the map of Bolivia must be added the small town of Calama in the new mining district of Caracolas.

EXPERIMENTAL farms are now being extended in the Madras presidency—a most essential step for agricultural improvement and practical instruction.

THE Government of Madras has been ordered to furnish special information on the Neilgherry nettle fibre plant.

ON the 5th July a most destructive typhoon attacked Hiogo, in Japan.

IN the same presidency, in the Parambalore district, a man-eating tiger has appeared, and killed four men, so that the Government has taken him into consideration, and placed a price of 30*l* on his head.

THE Island of Gorgona, off the coast of Choco, is much complained of by ship captains for its electric storms, and its irregular currents. It has held this reputation since the time of Pizarro.

A VALUABLE discovery of workable lead ore is announced from Jersey.

THE latest report from Tasmania in regard to the experiments for introducing salmon and trout into that country, shows that while the success of the cultivation of both is extremely probable, the existence of trout of large size is unmistakable.

COAL has been found in large quantities on the banks of a stream flowing into the Godavery, about 224 miles from Jugganet, and ninety-six from Budrachellum. It is close to the surface, and it is extremely probable that fresh deposits will be found in the adjacent British territory.

IT is to be noted that on the night of the 21st of August a very severe earthquake was felt at Callao, in Peru, at 8.32 P.M. The undulations were from N.W. to S.E. The shock was of fifteen seconds' duration. It was also felt severely at Cerro, Azul, and Pisco. The sea, which previously had been unusually calm, suddenly became very rough, and a strong southerly wind set in. For two days the sea remained very rough at Cerro Azul. The observations were confirmed by the steamship *Colon*. The shock severely shook the ship while it lasted. It was felt six miles to the westward of Chala Point at 8.50 P.M. ship time, and the sea almost immediately thereafter became agitated.

MEASURES are being taken by the Chilean Congress to prohibit the destruction of timber, particularly in the neighbourhood of springs. The timber districts of the provinces of Llanquihue, Valdivia, Chiloe, and of the Magellan territory are exempted from the law.

COCOS Island, in lat. 5° 30' N. in the Pacific Ocean, about 600 miles west of the Columbian coast, has now for some years been occasionally occupied by treasure seekers on a legend of a treasure buried by buccaners. At present it is again abandoned, but it is alleged a new expedition is organised. The island is not flat, as stated in many newspapers, but is volcanic, and 2,000 feet high. It is covered with timber and scrub, and being visited by frequent and heavy rains is always green. The place is riddled with shafts, some 150 feet deep. It produces nothing eatable.

THE valuable timber so abundant in the North Island of New Zealand is deserving of a better fate than to be cut down whole-sale and used as firewood. The rimu, or red pine, is most valuable for furniture and all ornamental work; the matai, or black pine, is more brittle and heavy than the other, but will take a most beautiful polish; whilst the totara, another so-called pine (for they are none of them Conifere), is easily worked both green and dry. There is also the rata, "that wonderful vegetable production forming itself out of numberless vines, which first receive their support from some full-grown tree, then enclose it in a deadly embrace, and gradually expel the remains of their foster parent as their own growing demands for space require to be satisfied, then finally uniting themselves form a solid tree, with all [the characteristics of bark, sap and heart, roots, trunk, and branch." This rata is almost the toughest wood known, and is used in many places for the cogs of wheels, &c. Besides these there are many others, especially the makia, which when thoroughly dry would turn or break the edge of the best axe ever produced in Sheffield, which are now only cut down for firewood as occasion requires.

THE GEOGNOSEY OF THE APPALACHIANS AND THE ORIGIN OF CRYSTALLINE ROCKS*

IN coming before you this evening my first duty is to announce the death of Prof. William Chauvenet. This sad event was not unexpected, since, at the time of his election to the presidency of the Association, at the close of our meeting at Salem in August 1869, it was already feared that failing health would prevent him from meeting with us at Troy, in 1870. This, as you are aware, was the case, and I was therefore called to preside over the Association in his stead. In the autumn of 1869, he was compelled by illness to resign his position of Chancellor of the Washington University of St. Louis, and in December last died at the age of fifty years, leaving behind him a record to which Science and his country may point with just pride. During his connection of fourteen years with the Naval Academy at Annapolis he was the chief instrument in building up that institution, which he left in 1859 to take the chair of Astronomy and Mathematics at St. Louis, where his remarkable qualities led to his selection, in 1862, for the post of Chancellor of the University, which he filled with great credit and usefulness up to the time of his resignation. It is not for me to pronounce the eulogy of Prof. Chauvenet, to speak of his profound attainments in astronomy and mathematics, or of his published works, which have already taken rank as classics in the literature of these sciences. Others more familiar with his field of labour may in proper time and place attempt the task. All who knew him can however join with me in testifying to his excellences as a man, an instructor, and a friend. In his assiduous devotion to scientific studies he did not neglect the more elegant arts, but was a skilful musician, and possessed of great general culture and refinement of taste. In his social and moral relations he was marked by rare elevation and purity of character, and has left to the world a standard of excellence in every relation of life which few can hope to attain.

In accordance with our custom it becomes my duty in quitting the honourable position of President, which I have filled for the past year, to address you upon some theme which shall be germane to the objects of the Association. The presiding officer, as you are aware, is generally chosen to represent alternately one of the two great sections into which the members of the Association are supposed to be divided, viz., the students of the natural-history sciences on the one hand, and of the physico-mathematical and chemical sciences on the other. The arrangement by which, in our organisation, geology is classed with the natural history division, is based upon what may fairly be challenged as a somewhat narrow conception of its scope and aims. While theoretical geology investigates the astronomical, physical, chemical, and biological laws which have presided over the development of our earth, and while practical geology or geognosy studies its natural history, as exhibited in its physical structure, its mineralogy and its palæontology, it will be seen that this comprehensive science is a stranger to none of the studies which are included in the plan of our Association, but rather sits like a sovereign, commanding in turn the services of all.

As a student of geology, I scarcely know with which section of the Association I should to-day identify myself. Let me endeavour rather to mediate between the two, and show you somewhat of the two-fold aspect which geological science presents, when viewed respectively from the stand-points of natural history and of chemistry. I can hardly do this better than in the discussion of a subject which for the last generation has afforded some of the most fascinating and perplexing problems for our geological students; viz., the history of the great Appalachian mountain chain. Nowhere else in the world has a mountain system of such geographical extent and such geological complexity been studied by such a number of zealous and learned investigators, and no other, it may be confidently asserted, has furnished such vast and important results to geological science. The laws of mountain structure, as revealed in the Appalachians by the labours of the brothers Henry D. and William B. Rogers, of Lesley and of Hall, have given to the world the basis of a correct system of orographic geology,† and many of the obscure geological problems of Europe become plain when read in the light of our American experience. To discuss even in the most

summary manner all of the questions which the theme suggests, would be a task too long for the present occasion, but I shall endeavour to-night in the first place to bring before you certain facts in the history of the physical structure, the mineralogy and the palæontology of the Appalachians; and in the second place to discuss some of the physical, chemical, and biological conditions which have presided over the formation of the ancient crystalline rocks that make up so large a portion of our great eastern mountain system.

I. THE GEOGNOSEY OF THE APPALACHIAN SYSTEM.—The age and geological relations of the crystalline stratified rocks of eastern North America have for a long time occupied the attention of geologists. A section across northern New York, from Ogdensburg on the St. Lawrence to Portland in Maine, shows the existence of three distinct regions of unlike crystalline schists. These are the Adirondacks to the west of Lake Champlain, the Green Mountains of Vermont, and the White Mountains of New Hampshire. The lithological and mineralogical differences between the rocks of these three regions are such as to have attracted the attention of some of the earlier observers. Eaton, one of the founders of American geology, at least as early as 1832, distinguished in his *Geological Text-book* (2nd edition) between the gneiss of the Adirondacks and that of the Green Mountains. Adopting the then received divisions of primary, transition, secondary and tertiary rocks, he divided each of these series into three classes, which he named carboniferous, quartzose, and calcareous; meaning by the first schistose or argillaceous strata schists, as, according to him, might include carbonaceous matter. These three divisions in fact corresponded to clay, sand, and lime-rocks, and were supposed by him to be repeated in the same order in each series. This was apparently the first recognition of that law of cycles in sedimentation upon which I afterwards insisted in 1863.* Without, so far as I am aware, defining the relations of the Adirondacks, he referred to the lowest or carboniferous division of the primary series the crystalline schists of the Green Mountains, while the quartzites and marbles at their western base were made the quartzose and calcareous divisions of this primary series. The argillites and sandstones lying still farther westward, but to the east of the Hudson River, were regarded as the first and second divisions of the transition series, and were followed by its calcareous division, which seems to have included the limestones of the Trenton group; all of these rocks being supposed to dip to the westward, and away from the central axis of the Green Mountains. Eaton does not appear to have studied the White Mountains, or to have considered their geological relations. They were, however, clearly distinguished from the former by C. T. Jackson in 1844, when, in his report on the geology of New Hampshire, he described the White Mountains as an axis of primary granite, gneiss, and mica-schist, overlaid successively, both to the east and west, by what were designated by him Cambrian and Silurian rocks; these names having, since the time of Eaton's publication, been introduced by English geologists. While these overlying rocks in Maine were unaltered, he conceived that the corresponding strata in Vermont, on the western side of the granitic axis, had been changed by the action of intrusive serpentines and intrusive quartzites, which had altered the Cambrian into the Green Mountain gneiss, and converted a portion of the fossiliferous Silurian limestones of the Champlain valley into white marbles.† Jackson did not institute any comparison between the rocks of the White Mountains and these of the Adirondacks; but the Messrs. Rogers in the same year, 1844, published an essay on the geological age of the White Mountains, in which, while endeavouring to show their Upper Silurian age, they speak of them as having been hitherto regarded as consisting exclusively of various modifications of granitic and gneissoid rocks, and as belonging "to the so-called primary periods of geologic time."‡ They however considered that these rocks had rather the aspect of altered palæozoic strata, and suggested that they might be, in part at least, of the age of the Clinton division of the New York system; a view which was supported by the presence of what were at the time regarded by the Messrs. Rogers as organic remains. Subsequently, in 1847,§ they announced that they no longer considered these to be of organic origin, without however retracting their opinion as to the palæozoic age of the strata. Reverting to another place in my address the discussion of the geological age of the White Mountain rocks, I proceed to notice briefly the

distinctive characters of the three groups of crystalline strata just mentioned, which will be shown in the sequel to have an importance in geology beyond the limits of the Appalachians.

1. *The Adirondack or Laurentide Series*.—The rocks of this series, to which the name of the Laurentian system has been given, may be described as chiefly firm granitic gneisses, often very coarse-grained, and generally reddish or grayish in colour. They are frequently hornblende, but seldom or never contain much mica, and the mica-schist (often accompanied with staurolite, garnet, andalusite, and cyanite), so often characteristic of the White Mountain series, are wanting among the Laurentian rocks. They are also destitute of argillites, which are found in the other two series. The quartzites, and the pyroxenic and hornblende rocks, associated with great formations of crystalline limestone, with graphite, and immense beds of magnetic iron ore, give a peculiar character to portions of the Laurentian system.

2. *The Green Mountain Series*.—The quartzo-feldspathic rocks of this series are to a considerable extent represented by a fine-grained petrosilex or euriite, though they often assume the form of a true gneiss, which is ordinarily more micaceous than the typical Laurentian gneiss. The coarse-grained, porphyritic, reddish varieties common to the latter are wanting to the Green Mountains, where the gneiss is generally of pale greenish and grayish hues. Massive stratified diorites, and epidotic and chloritic rocks, often more or less schistose, with staurolite, dark-coloured serpentines and feriferous dolomites and magnesites, also characterise this gneissic series, and are intimately associated with beds of iron ore, generally a slaty hematite, but occasionally magnetite. Chrome, titanium, nickel, copper, antimony, and gold are frequently met with in this series. The gneisses often pass into schistose micaceous quartzites, and the argillites, which abound, frequently assume a soft, unctuous character, which has acquired for them the name of talcose or nacreous slates, though analysis shows them not to be magnesian, but to consist essentially of a hydrous micaceous mineral. They are sometimes black and graphitic.

3. *The White Mountain Series*.—This series is characterised by the predominance of well-defined mica-schists, interstratified with micaceous gneisses. These latter are ordinarily light-coloured from the presence of white feldspar, and though generally fine in texture, are sometimes coarse-grained and porphyritic. They are less strong and coherent than the gneisses of the Laurentian, and pass, through the predominance of mica, into mica-schists, which are themselves more or less tender and friable, and present every variety, from a coarse gneiss-like aggregate down to a fine-grained schist, which passes into argillite. The micaceous schists of this series are generally much richer in mica than those of the preceding series, and often contain a large proportion of well-defined crystalline tables belonging to the species muscovite. The cleavage of these micaceous schists is generally, if not always, coincident with the bedding, but the plates of mica in the coarser-grained varieties are often arranged at various angles to the cleavage and bedding-plane, showing that they were developed after sedimentation, by crystallisation in the mass, a circumstance which distinguishes them from rocks derived from the ruins of these, which are met with in more recent series. The White Mountain rocks also include beds of micaceous quartzite. The basic silicates in this series are represented chiefly by dark-coloured gneisses and schists, in which hornblende takes the place of mica. These pass occasionally into beds of dark hornblende-rock, sometimes holding garnets. Beds of crystalline limestone occasionally occur in the schists of the White Mountain series, and are sometimes accompanied by pyroxene, garnet, idocrase, zircon, and graphite, as in the corresponding rocks of the Laurentian, which this series, in its more gneissic portions, closely resembles, though apparently distinct geognostically. The limestones are intimately associated with the highly micaceous schists, containing staurolite, andalusite, cyanite, and garnet. These schists are sometimes highly plumbaginous, as seen in the graphitic mica-schist holding garnets in Nelson, New Hampshire, and that associated with cyanite in Cornwall, Conn. To this third series of crystalline schists belong the concretionary granitic veins abounding in beryl, tourmaline, and lepidolite, and occasionally containing tinstone and columbite. Granitic veins in the Laurentian gneisses frequently contain tourmaline, but have not, so far as is yet known, yielded the other mineral species just mentioned.*

II. THE ORIGIN OF CRYSTALLINE ROCKS.—We now ap-

* Hunt, Notes on Granitic Rocks; Amer. Jour. Sci., III. i. 182.

proach the second part of our subject, namely, the genesis of the crystalline schists. The origin of the mineral silicates, which make up a great portion of the crystalline rocks of the earth's surface, is a question of much geological interest, which has been to a great degree overlooked. The gneisses, mica-schists, and argillites, of various geological periods do not differ very greatly in chemical constitution from modern mechanical sediments, and are now very generally regarded as resulting from a molecular re-arrangement of similar sediments formed in earlier times by the disintegration of previously existing rocks not very unlike them in composition; the oldest known formations being still composed of crystalline stratified deposits presumed to be of sedimentary origin. Before these the imagination conceives yet earlier rocks, until we reach the surface of unstratified material, which the globe may be supposed to have presented before water had begun its work. It is not, however, my present plan to consider this far off beginning of sedimentary rocks, which I have elsewhere discussed.†

Apart from the clay and sand-rocks just referred to, whose composition may be said to be essentially quartz and aluminous silicates, chiefly in the forms of feldspar and mica, or the results of their partial decomposition and disintegration, there is another class of crystalline silicated rocks which, though far less important in bulk than the last, is of great and varied interest to the lithologist, the mineralogist, the geologist, and the chemist. The rocks of this second class may be defined as consisting in great part of the silicates of the protoxyd bases, lime, magnesia, and ferrous oxyd, either alone, or in combination with silicates of alumina and alkalis. They include the following as their chief constituent mineral species:—Pyroxene, hornblende, olivine, serpentine, talc, chlorite, epidote, garnet, and tridacite feldspars, such as labradorite. The great types of this second class are not less well defined than the first, and consist of pyroxenic and hornblende rocks, passing into diorites, diabases, ophiolites and talcose, chloritic and epidotic rocks. Intermediate varieties resulting from the association of the minerals of this class with those of the first, and also with the materials of non-silicated rocks, such as limestones and dolomites, show an occasional blending of the conditions under which these various types of rocks were formed.

The distinctions just drawn between the two great divisions of silicated rocks are not confined to stratified deposits, but are equally well marked in eruptive and unstratified masses, among which the first type is represented by trachytes and granites, and the second by dolerites and diorites. This fundamental difference between acid and basic rocks, as the two classes are called, finds its expression in the theories of Phillips, Durocher, and Bunsen, who have deduced all silicated rocks from two supposed layers of molten matter within the earth's crust, consisting respectively of acid and basic mixtures; the trachytic and pyroxenic magmas of Bunsen. From these, by a process of partial crystallisation and eliquation, or by commingling in various proportions, those eruptive rocks which depart more or less from the normal types are supposed by the theorists of this school to be generated.† The doctrine that these eruptive rocks are not derived directly from a hitherto uncongealed nucleus, but are softened and crystallised sediments, in fact that the whole of the rocks at present known to us have at one time been aqueous deposits, has, however, found its advocates. In support of this view, I have endeavoured to show that the natural result of forces constantly in operation tends to resolve the various igneous rocks into two classes of sediments, in which the two types are, to a great extent, preserved. The mechanical and chemical agencies which transform the crystalline rocks into sediments, separate these more or less completely into coarse, sandy, permeable beds on the one hand, and fine clayey impervious muds on the other. The action of infiltrating atmospheric waters on the first and more silicious strata, removes from them lime, magnesia, iron-oxyd, and soda, leaving behind silica, alumina, and potash—the elements of granitic, gneissic, and trachytic rocks. The finer and more aluminous sediments, including the ruins of the soft and easily abraded silicates of the pyroxene group, resisting the penetration of the water, will, on the contrary, retain their alkalis, lime, magnesia, and iron, and thus will have the composition of the more basic rocks.‡

A little consideration will, however, show that this process, although doubtless a true cause of differences in the composition of

‡ Quar. Jour. Geol. Soc., XV. 439; also, Amer. Jour. Sci., II. xxx. 131.

sedimentary rocks, is not the only one, and is inadequate to explain the production of many of the varieties of stratified silicated rocks, such as serpentine, steatite, hornblende, diallage, chlorite, pinitic, and labradorite, all of which mineral species form rock masses by themselves, frequently almost without admixture. No geological student will now question that all of these rocks occur as members of stratified formations. Moreover, the manner in which serpentines are found interstratified with steatite, chlorite, argillite, diorite, hornblende, and feldspar rocks, and these, in their turn, with quartzites and orthoclase rocks, is such as to forbid the notion that these various materials have been deposited, with their present composition, as mechanical sediments from the ruins of pre-existing rocks; a hypothesis as untenable as that ancient one which supposed them to be the direct results of plutonic action.

There are, however, two other hypotheses which have been proposed to explain the origin of these various silicated rocks, and especially of the less abundant, and, as it were, exceptional species just mentioned. The first of these supposes that the minerals of which they are composed have resulted from an alteration of previously existing minerals, often very unlike in composition to the present, by the taking away of certain elements and the addition of certain others. This is the theory of metamorphism by pseudomorphic changes, as they are called, and is the one taught by the now reigning school of chemical geologists, of which the learned and laborious Bischof, whose recent death science deplores, may be regarded as the great exponent. The second hypothesis supposes that the elements of these various rocks were originally deposited as, for the most part, chemically formed sediments, or precipitates; and that the subsequent changes have been simply molecular, or, at most, confined in certain cases to reactions between the mingled elements of the sediments, with the elimination of water and carbonic acid. It is proposed to consider briefly these two opposite theories, which seek to explain the origin of the rocks in question respectively by pseudomorphic changes in pre-existing crystalline rocks, and by the crystallisation of aqueous sediments, for the most part chemically-formed precipitates.

Mineral pseudomorphism, that is to say, the assumption by one mineral substance of the crystalline form of another, may arise in several ways. First of these is the filling up of a mould left by the solution or decomposition of an imbedded crystal, a process which sometimes takes place in mineral veins, where the processes of solution and decomposition can be freely carried on. Allied to this, is the mineralisation of organic remains, where carbonate of lime or silica, for example, fills the pores of wood. When subsequent decay removes the woody tissue, the vacant spaces may, in their turn, be filled by the same or another species.* In the second place, we may consider pseudomorphs from alteration, which are the result of a gradual change in the composition of a mineral species. This process is exemplified in the conversion of feldspar into kaolin by the loss of its alkali and a portion of silica, and the fixation of water, or in the change of chalybite into limonite by the loss of carbonic acid and the absorption of water and oxygen.

The doctrine of pseudomorphism by alteration as taught by Gustav Rose, Haidinger, Blum, Volger, Rammelsberg, Dana, Bischof, and many others, leads them, however, to admit still greater and more remarkable changes than these, and to maintain the possibility of converting almost any silicate into any other. Thus, by referring to the pages of Bischof's *Lehrbuch der Geognosie*, it will be found that serpentine is said to exist as a pseudomorph after augite, hornblende, olivine, clionodrite, garnet, mica, and probably also after labradorite, and even orthoclase. Serpentine rock or ophiolite is supposed to have resulted, in different cases, from the alteration of hornblende-rock, diorite, granulite, and even granite. Not only silicates of protoxys and aluminous silicates are conceived to be capable of this transformation, but probably also quartz itself; at least, Blum asserts that meerschaum, a closely related silicate of magnesia, which sometimes accompanies serpentine, results from the alteration of flint, while, according to Rose, serpentine may even be produced from dolomite, which we are told is itself produced by the alteration of limestone. But this is not all—feldspar may replace carbonate of lime, and carbonate of lime feldspar, so that, according to Volger, some gneissoid limestones are probably formed from gneiss by the substitution of calcite for orthoclase. In this way we are led from gneiss or granite to limestone, from limestone to dolomite, and from dolomite to serpentine, or more directly from granite, granulite, or diorite to serpentine at once, without passing

through the intermediate stages of limestone and dolomite, till we are ready to exclaim in the words of Goethe:—

"Aich ängstet das Verflingliche
Im widrigen Geschwätz
Wo Nichts verharret, Alles flieht,
Wo schon verschwunden was man si-ht,"

which we may thus translate:—"I am vexed with the sophistry in their contary jargon, where nothing endures, but all is fugitive, and where what we see has already passed away."

By far the greater number of cases on which this general theory of pseudomorphism by a slow process of alteration in minerals, has been based, are, as I shall endeavour to show, examples of the phenomenon of mineral envelopment, so well studied by Delesse in his essay on pseudomorphs,† and I may be considered under two heads:—first, that of symmetrical envelopment, in which one mineral species is so enclosed within the other that the two appear to form a single crystalline individual. Examples of this are seen when prisms of cyanite are surrounded by staurolite, or staurolite crystals completely enveloped in those of cyanite, the vertical axes of the two prisms corresponding. Similar cases are seen in the enclosure of a prism of red in an envelope of green tourmaline, of allanite in epidote, and of various minerals of the pyroxene group in one another. The occurrence of muscovite in lepidolite, and of margarodite in lepidomalene, or the inverse, are well-known examples, and, according to Scheerer, the crystallisation of serpentine around a nucleus of olivine is a similar case. This phenomenon of symmetrical envelopment, as remarked by Delesse, shows itself with species which are generally isomorphous or homeomorphous, and of related chemical composition. Allied to this is the repeated alternation of crystalline laminae of related species, as in perthite, the crystalline cleavable masses of which consist of thin alternating layers of orthoclase and albite.

Very unlike to the above are those cases of envelopment in which no relations of crystalline symmetry nor of similar chemical constitution can be traced. Examples of this kind are seen in garnet crystals, the walls of which are shells, sometimes no thicker than paper, enclosing in different cases crystalline carbonate of lime, epidote, chlorite, or quartz. In like manner, crystalline shells of leucite enclose feldspar, hollow prisms of tourmaline are filled with crystals of mica or with hydrous peroxyl of iron, and crystals of beryl with a granular mixture of orthoclase and quartz, holding small crystals of garnet and tourmaline, a composition identical with the enclosing granitic vein-stone.‡ Similar shells of galenite and of zircon, having the external forms of these species, are also found filled with calcite. In many of these cases the process seems to have been first the formation of a hollow mould or skeleton crystal (a phenomenon sometimes observed in salts crystallising from solutions), the cavity being sometimes filled with other matters. Such a process is conceivable in free crystals found in veins, as for example, galenite, zircon, tourmaline, beryl, and some examples of garnet, but is not so intelligible in the case of those garnets imbedded in mica-schist, studied by Delesse, which enclosed within their crystalline shells irregular masses of white quartz, with some little admixture of garnet. Delesse conceives these and similar cases to be produced by a process analogous to that seen in the crystallisation of calcite in the Fontainebleau sandstone; where the quartz grains, mechanically enclosed in well-defined rhombohedral crystals, equal, according to him, sixty-five per cent. of the mass. Very similar to these are the crystalloids with the form of orthoclase, which sometimes consist in large part of a granular mixture of quartz, mica, and orthoclase, with a little cassiterite, and in other cases, contain two thirds their weight of the latter mineral, with an admixture of orthoclase and quartz. Crystals with the form of scapolite, but made up, in a great part, of mica, seem to be like cases of envelopment, in which a small proportion of one substance in the act of crystallisation, compels into its own crystalline form a large portion of some foreign material, which may even so mask the crystallising element that this becomes overlooked, as of secondary importance. The substance which, under the name of houghtite, has been described as an altered spinel, is found by analysis to be the mixture of villknerite with a variable proportion of spinel, which in some specimens, does not exceed eight per cent., but to which, nevertheless, these crystalloids appear to owe their more or less complete octohedral form.‡

INSTRUCTIONS FOR OBSERVERS, AT THE ENGLISH GOVERNMENT ECLIPSE EXPE- DITION, 1871

II.—POLARISCOPIC OBSERVATIONS

THE chief points to which observers of polarisation should direct their attention appear to be:—

- A. What is the nature of the outlying corona?
- B. Can the radial polarisation of the circumsolar corona be traced down to the photosphere, or, if not, how low?
- C. Is secondary atmospheric polarisation traceable? and if so, does the plane change during totality?

A. We might suppose this to be due—

- (1) to circumsolar matter (though at a great distance from the sun) reflecting light,
- (2) to circumsolar matter in the state of self-luminous gas,
- (3) to circumlunar matter diffracting and, to a certain extent, reflecting light (most improbable),
- (4) to lofty atmospheric haze or cloud, of excessive tenuity, diffracting light.

The light ought to be, for

- (1) strongly and radially polarised,
- (2) unpolarised,
- (3) and (4) insensibly or all but insensibly polarised.

Hence polarisation observations would only serve to discriminate between (1) on the one hand, and (2), (3), or (4) on the other.

From the faintness of the object and its considerable extent, the naked eye, armed with a polariscope, might be best. If a telescope be used, it should be of quite low power, and the aperture as large as the breadth of the pupil multiplied by the magnifying-power.

Suppose the polariscope be Savart's, the quartz plates being thick enough (if the naked eye be used) to give bands as narrow as, say, $20''$ diameter.

FIG. 1.

Let the observer rotate the polariscope till the bands, if any, seen on the dark moon disappear; then, *without rotating the instrument round its axis*, let him incline the axis so as to point at the outlying corona in different directions round the sun, and notice whether the bands spring into existence; and if so, let him sweep round the sun, noticing what lies *outside* the clearly circumsolar corona of $5'$ or so height, and let him notice particularly by estimation the direction, relatively to the bands, of the radius vector of the region where they are most vivid, or, better, the azimuth of both radius and bands. He should also specify, *provided he can do so with certainty*, whether the bands were black-centred or white-centred. He should also state in his account, and verify the statement by an observation made at leisure before or after totality, whether his Savart is constructed (or set) so as to have the bands *parallel* or *perpendicular* to the principal plane of the Nicol.

A very useful adjunct to a Savart's polariscope would be a glass reflector, or else a tourmaline, placed so as to cover a small segment of the field of view near the edge. On account of the possible difficulty of illuminating the reflector in the peculiar circumstances of a total eclipse, a tourmaline would seem to be preferable. It should be placed for the naked eye at the least distance of distinct vision—for a telescope, in or in front of the eye-piece, where a real image is formed so as to be seen distinctly—the axis of the tourmaline being parallel to the edge or chord of the segment, and the bands being set perpendicular to this chord. In the event of rotation during the observation, the whole should be rotated together. The question whether the bands are bright-centred or dark-centred, which, in the case of slight polarisation, is difficult to decide, would thus be replaced by the simpler question, whether the bands in the field were of the same character as in the segment (*i.e.*, bright being a prolongation of bright, and dark of dark) or of opposite character.

The observer should previously have practised on the blue sky, rotating his Savart till the bands disappear, and noticing to what degree they are brought back by small changes of pointing without rotation, so as to be prepared for what he is liable to from secondary atmospheric polarisation during totality.

Should only very feeble bands be seen in the outer corona, such as might possibly be attributable to atmospheric polarisation operating through small changes of pointing, it would be well for control to rotate the instrument a *little* till bands are fairly visible on the disc of the moon, and notice whether on passing to the outer corona, in *whatever* direction, the bands, instead of being reinforced, tend rather to be drowned in white light. Should luminous beams or dark rifts be seen in the outer corona, so as to exhibit contrast of light and shade in close proximity, a good opportunity will be afforded of testing whether the light of the outer corona is polarised or not. If it be polarised, then on rotating the Savart, so as to make the bands cut at various indications the boundary of light and shade, the bands will in certain azimuths of the Savart be stronger on the luminous than on the dark side of the edge of the beam or rift. If it be unpolarised, then, whatever be the azimuth of the Savart, the bands will be rather drowned in white light than reinforced on passing from the dark to the luminous side of the edge.

But Savart's and other colour-polariscopes, which are admirable for detecting a slight polarisation in light which is not particularly feeble, break down when the difficulty arises from the feebleness of the light rather than the slowness of the polarisation. In such cases a simple double-image prism, with a diaphragm-tube, is better. Unless those who have seen total eclipses can decide from trial (suppose on the clear sky after sunset, or at night when illuminated by the moon), combined with

FIG. 2.

their memory of the degree of illumination of the outer corona, it might be well that the observer should be provided with and should try both instruments.

B. For this a telescope will be required with a magnifying power of, say, 16 or 20. A biquartz seems the best instrument, placed at the common focus of the eye-piece (which should be positive) and objective, and combined with a Nicol's prism, or, if it can be procured, a thoroughly good tourmaline. A tourmaline might be placed over the eye-hole, whereas a Nicol might have to be placed in the body of the eye-piece, which, however, is no particular disadvantage if properly done.

Let it be ascertained by previous trial how much a Nicol must be turned from the position in which the two halves are purple alike to make the tints contrast more vividly. Say it is 30° . Suppose the observer on the line of central shadow, so that the limits of disappearance and reappearance will be on opposite ends of a diameter. The biquartz and Nicol have been relatively set so that the line of junction is in the plane of polarisation of light extinguished by the Nicol, turn them together before totality 30° (or whatever other angle may have been fixed on) to either side of the diameter of disappearance, and, pointing the telescope to the place of disappearance (Fig. 1), await totality without dazzling the eye. The moment the sun is covered, apply the eye to the telescope, and notice whether there is a vivid contrast of colour right and left of the line of junction of the quartz plates *all the way down to the dark moon* (Fig. 2), or only in the higher parts of the circumsolar corona.

Be ready to repeat the observation before reappearance, with the telescope pointed to the place of reappearance; and meanwhile, if time permits, repeat Prazmou-ki's observation by pointing the telescope, without rotation of the analyser, so that the line of junction bisects the moon, and noticing whether the semi-

circles of the corona are purple alike where they abut on the junction, and what is the order of colours in the semicircle on receding from the junction. A record as to which is which of the two halves of the biquartz should be carefully preserved.

Should secondary atmospheric polarisation be so strong as to throw doubt on the results (which may be judged of by noticing the light on the dark moon), it would be well to rotate the analyser till the two halves seen on the dark moon are purple alike, and then after the pointing of the telescope, and repeat Prazmowski's observation.

It will be observed that the same general principles apply to the elimination of atmospheric polarisation, whether the polariscope employed be a Savart's polariscope, a polariscope with quartz wedges, or a biquartz polariscope.

C. This is of little intrinsic interest, its chief use being to clear up possible doubts as to the results obtained by the observers of A and B. Should there be an observer not otherwise employed, he might be deputed to observe the direction of the Savart's bands on disappearance, both on the dark moon and the surrounding sky, and whether this direction changes during totality. Also it should be specified in which pair of opposite quadrants they were black-centred and in which white-centred. Should this be found impossible or uncertain (the instrument being unprovided with the adjunct mentioned above), the Savart might be used as a simple Nicol by turning it end for end, so that the quartz plates are next the eye; and with this the plane of polarisation might be roughly determined by means of the azimuth of the principal plane of the Nicol when the light most nearly disappears.

Should registration of the azimuth be attempted, the Savart would be fixed so as not to be reversible. In that case the observer might be provided with a double-image prism and diaphragm-tube for separate use in case of need.

Stoppage of stray light in a telescope designed for polarisation

The want of this appears to have occasioned some difficulty at the last eclipse.

The simplest way is by a stop, with a hole just large enough to contain the image of the object-glass. Such exists in the erecting eye-piece, where an image of the object-glass is formed in the body of the eye-piece. It exists too, in a Gregorian or Cassegrainian telescope, where the stoppage is imperative. But in an ordinary refracting telescope, with an inverting eye-piece, the eye-hole (from certain motives of convenience) is larger than in front of (*i. e.* nearer the object-glass than) the bright circle, or image of the object-glass; and unless the tube is sufficiently provided with stops, when a faint object near a bright one is looked at, light from the bright, reflected from the inside of the tube, is liable to enter the field of view. Large instruments are provided with stops; but I fancy smaller instruments are sometimes turned out without them. This should be looked to.

The observer may test the correctness of stopping by taking out the eye-piece, inserting a paper disc with a central hole of the size of the field-glass, turning the instrument nearly but not quite to a bright object, as well as to points more distant from the bright object, and noticing whether the side of the tube, even when viewed in a direction grazing the edge of the hole, is properly dark, so that only the edges of the stops are seen.* On the other hand, the stops should not obstruct a clear view of the object-glass as seen through the hole representing the field-glass, or they will render the outer portions of the object-glass useless.

General Remarks

I consider the observation recommended by Mr. Ranyard (see NATURE, Aug. 24, 1871), very important, if, after what Prazmowski and Ranyard have done, the point be still deemed doubtful. Prazmowski's observation seems to have been beautifully devised and executed, but carelessly described. It is only by conjecture that I can make sense and harmony with what is known, out of his observations as described by himself. But I think that Mr. Ranyard has at least shown that our conjectural interpretation of Prazmowski's observation is the right one; and if so, the point seems settled.

It is for this reason that, in lieu of No. 3, first half, I proposed something new. What becomes of the magnesium, &c., which the spectroscopist reveals low down in the gigantic puffs which the sun emits? The hydrogen must surely carry the magnesium, &c., with it to the higher regions, though the magnesium, &c., would soon be condensed, and so would not be detected by the spectroscopist. These substances would exist in the form of an

exceedingly fine haze or dust. I use the two words, "haze" to denote a filmy cloud of molten "dust" of solid matter. This haze or dust is capable of detection, and, according to my interpretation, has been detected, by polarisation; and it is interesting to know how low down it can be detected. Mr. Stoney's speculations as to layers are utterly inapplicable here, as they imply a state of tranquillity quite unlike what we now know to exist, at any rate in connexion with the puffs.

I don't know why, in the second half of No. 3, Mr. Ranyard prescribes placing the line of junction across a sector or rift, if by that he means turning the eye-piece carrying the quartz plates so that the line is perpendicular with the corona to the sector. It would be more likely to yield results if it cut it obliquely, as represented for the corona in Fig. 2. But probably he only means pointing the telescope so that the junction cuts the rift. If the observer notices contrasting colours, he may then proceed to determine the plane of polarisation. G. G. S.

SCIENTIFIC SERIALS

THE *Journal of the Quekett Microscopical Club*, No. 16. October 1871. "Microscopic Work and Conjectural Science," being the address of the President (Lionel S. Beale, M.B., F.R.S.), for the year 1871. This address is chiefly occupied in combating the method, presumed to have been adopted, of depreciating one kind of scientific investigation in order to elevate another, and attacks without ceremony those who would elevate physical science to the disparagement of microscopic observation.—"On the Examination of the Surface Markings of Diatoms by the Oxy-calcium Light," by N. E. Green. The writer of this paper details his examination of such diatoms as *Isthmia*, *Biddulphia*, *Triceratium*, *Pleurosigma*, &c., as opaque objects by high powers, as one-sixth Ross and one-twelfth Gundlach, through the agency of the oxy-calcium light. The conclusion at which he has arrived is, that the markings on all the above, except *Pleurosigma*, resemble "craters," the surface "being studded with rows of small shallow craters, the sharp edges of which projected slightly above, while the centres seemed to be below the surface." In *Pleurosigma* a different structure of the surface was observed. "The lime light brought out most distinctly the bead-like character of its markings; they stood out in bold relief like rows of Indian corn."—"The Inaugural Address of the South London Microscopical and Natural History Club, by R. Braithwaite, M.D., F.L.S., is principally devoted to suggestions on the vast field for observation at the disposal of the microscopist.—"On Nucleated Sporida," by M. C. Cooke, M.A. After describing the general structure which prevails in the genus *Peziza* of Ascomycetous Fungi, the writer details his method of mounting sections for the microscope in pure glycerine. The nucleated sporida, so prevalent in this genus, are affirmed to be so affected by this method that in a short time all traces of the nuclei are lost, and the object of the paper is to indicate the doubtful value of nucleated sporida in specific characters. The true nature of such nuclei and their uses are said to be obscure.

In the *Revue Scientifique*, Nos. 13—18, are many valuable articles. Further reports are given of the proceedings of the Edinburgh meeting of the British Association, and a translation of Prof. T. Sterry Hunt's address to the Indianapolis meeting of the American Association. We have also a memoir of M. Latet by M. G. de Mortillet; Helmholtz's paper on the rapidity of propagation of electro-dynamical actions; report of M. Chauveau's lectures on the physiology of virulent maladies; a lecture by M. Claude Bernard on the method and principle of physiology; a translation of P. Secchi's paper on the solar protuberances from the *Atti dell' Accademia pontificia de nuovi Lincei*; a biographical sketch of Haidinger by M. Fouqué; reports of the proceedings of the various scientific institutions in France and Belgium; and translations of lectures delivered at the Royal Institution, University of Edinburgh, &c., by Prof. Tyndall, Dr. Carpenter, Dr. Laycock, and others.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 23.—The greater part of the communications read at this meeting were devoted to chemical subjects. Of mathematical papers only one was presented—namely, a continuation of M. Chasles' memoir on the determination of a series of groups of a certain number of points on a geometrical curve.—A note was read by M. J. Bertrand on the

* If reflection occurs from the part of the tube so near the eye as not to appear within the field, it will not signify much.

mathematical theory of dynamical electricity, and a memoir by M. E. Mathieu on the integration of equations to the partial differences of mathematical physics.—M. du Moncel presented some observations relating to a recent communication by M. Ruhmkorff upon some experiments in magneto-electric induction, in which he claimed to have already ascertained and published facts analogous to those of the German author.—M. P. A. Favre read a continuation of his thermic researches upon the electrolysis of the hydracids.—A fifth letter from Father Secchi on the various aspects of the protuberances and other remarkable parts of the surface of the sun was read, in which he describes the results of simultaneous observations made by himself at Rome, and by M. Tacchini at Palermo.—M. Secchi also presented a note on a new method of observing the eclipses and passages of Venus, by means of a spectroscopic apparatus modified by having at a distance of about 20 centimetres in front of the spectroscope, an additional prism having its refringent angle parallel to the fissure.—The chemical papers were as follows:—a theory of simple reactions limited by inverse action, and an application of the same to the transformations of phosphorus, by M. J. Lemoine.—Researches in chemical statics, by M. Stas, containing a discussion of the phenomena which occur in the precipitation of dilute solutions of salts of silver by hydrochloric, hydrobromic, and hydriodic acids, and by chlorides, bromides, and iodides. This paper contains some results of great importance in the analysis of bodies containing silver.—The conclusion of the second part of M. Berthelot's investigation of the ammoniacal salts.—A note on the transformation of glucoses into monomitic and hexamitic alcohols, by M. G. Bouchardat, communicated by M. A. Wurtz. The author acts upon the glucoses by means of an amalgam of sodium. He describes its action upon glucose and sugar of milk.—A note on the hexabromide and hexachloride of silicon, by M. C. Friedel, also presented by M. A. Wurtz; and a note on the method of determining the gases evolved by an explosion of nitroglycerine, by M. L. L'Hôte, presented by General Morin. From the researches of the last-mentioned author it appears that 1 gramme of nitroglycerine produces 284 cub. centim. of gas, containing by volume 45.72 of carbonic acid, 20.36 of dioxide of nitrogen, and 33.92 of nitrogen.—M. Elie de Beaumont called attention to some specimens of native phosphate of lime from Caylux and Cajare, and noticed the importance of these deposits for agricultural purposes. M. Combes also remarked upon this subject.—M. Chapelas presented a note on a remarkable meteor observed during the night of the 19th October.

PHILADELPHIA

Academy of Natural Sciences, May 9.—The President, Dr. Ruschenberger, in the chair.—Prof. Cope demonstrated some anatomical points of importance in the classification of some of the Siluroids of the Amazon, noticing first those which have no swimming bladder, but having the post-temporal bone pierced in a sieve-like manner, forming minute tympana; these he characterised as *Otocinclus*. Others having huge swim-bladders, gun-boat style of shape. No adipose fin; the back naked. No lyre plate, indicated as *Zathorax*. A third, body protected by bony shields above. No adipose fin; the scapular arch dermoossified and lyre-shaped below; indicated as *Physopyxis lyra*. A fourth, shielded all over its sides, with the under lip turned back, genus *Corydoras*. A fifth, where the under lip is separated, except at the ends, forming loops, named *Brechia*. In the sixth, where the lips are separated from the beard distally forming chin beards, indicated as *Dianema*.

May 16.—Dr. Carson, Vice-President, in the chair.—"Remains of Mastodon and Horse in North Carolina."—Prof. Leidy exhibited two photographs, received from Prof. W. C. Kerr, State Geologist of North Carolina, representing some remains of *Mastodon americanus* found in that State. One of the specimens represented is that of the greater part of the lower jaw of a mature male, retaining both incisor tusks and the last two molar teeth. The latter, with their angular lobes separated by deep angular and nearly unobstructed valleys, are quite characteristic of the species. The incisors are an inch and three-fourths in diameter. The last molar has four transverse pairs of lobes and a well-developed heel. The penultimate molar has three transverse pairs of lobes. The specimen was obtained from gravel overlying the miocene marl near Goldsboro', Lenoir Co., N.C. An isolated last lower molar of the same species, represented in company with the jaw, was obtained in Pitt Co.—Prof. Leidy also exhibited a specimen of an upper molar tooth, which Mr. Timothy Conrad had picked up from a pile of miocene marl at

Greenville, Pitt Co., N.C. He suspected, from its size and intricacy in the folding of the enamel of the i-les at the middle of the triturating surface, that the tooth belonged to the post-pliocene *Equus complicatus*, and was an accidental occupant of the miocene marl. It may, however, belong to a Hipparion of the miocene period, but the imperfection of the specimen at its inner part prevented its positive generic determination.

THE ORIGIN OF GENERA *

ALTHOUGH it is now two years since the publication of Prof. Cope's "fragmentary essay," as he modestly terms it, bearing the above title, it may not be out of place, in the present stage of the theory of Evolution, to give our readers some idea of its scope. It ought to be in the possession of every naturalist. Although already so condensed that anything like an analysis of it is impossible, the following tabular sketch may serve to give our readers an idea of the mode in which the Origin of Genera is treated:—

I. Relations of allied genera.

First; in adult age.

Second; in relation to their development.

a. On exact parallelism.

β. On inexact or remote parallelism.

γ. On parallelism in higher groups.

δ. On the extent of parallelisms.

II. Of retardation and acceleration in generic characters.

First; metamorphoses in adult age.

a. The developmental relations of generic and specific characters.

β. Probable cases of transition.

γ. Ascertained cases of transition.

Second; earlier metamorphoses.

δ. The origin of inexact parallelisms.

III. Relations of higher groups.

a. Of homologous groups.

β. Of heterology.

γ. Of mimetic analogy.

IV. Of natural selection.

a. As affecting class and ordinal characters.

β. As affecting family characters.

γ. As affecting generic characters.

δ. As affecting specific characters.

e. On metaphysical species.

V. Of epochal relations.

Professor Cope considers that the laws which have regulated the successive creation of organic beings are of two kinds. The first, that which has impelled matter to produce numberless ultimate types from common origins; the second, that which expresses the mode or manner in which the first law has executed its course, from its commencement to its determined end, in the many cases before us.

"That a descent, with modifications, has progressed from the beginning of the creation is exceedingly probable. The best enumerations of facts and arguments in its favour are those of Darwin, as given in his various important works, 'The Origin of Species,' &c. There are, however, some views respecting the laws of development on which he does not dwell, and which it is proposed here to point out.

"In the first place, it is an undoubted fact that the origin of genera is a more distinct subject from the origin of species than has been supposed.

"A descent with modification involves continuous series of organic types through one or many geologic ages, and

the co-existence of such parts of such various series at one time as the law of mutual adaptation may permit.

"These series, as now found, are of two kinds: the uninterrupted line of specific, and the same uninterrupted line of generic characters. These are independent of each other, and have not, it appears to the writer, been developed *pari passu*. As a general law, it is proposed to render highly probable that the same specific form has existed through a succession of genera, and perhaps in different epochs of geologic time.

"With regard to the first law of development as above proposed, no one has found means of discovering it, and perhaps no one ever will. It would answer such questions as this. What necessary coincidence of forces has resulted in the terminus of the series of fishes in the perches as its most specialised extreme? or, of the batrachia, in the fresh-water frogs, as its ultimum? or, of the thrushes, among birds, as their highest extreme? in a word, what necessity resulted in man as the crown of the mammalian series, instead of some other organic type? Our only answer and law for the questions must be, the will of the Creator.

"The second law of modes and means has been represented to be that of natural selection by Darwin. This is, in brief, that the will of the animal applied to its body in the search for means of subsistence and protection from injuries gradually produces those features which are evidently adaptive in their nature. That, in addition, a disposition to a general variation on the part of species has been met by the greater or less adaptation of the results of such variation to the varying necessities of their respective situations. That the result of such conflict has been the extinction of those types that are not adapted to their immediate or changed conditions, and the preservation of those that are" (pp. 4, 5).

In the chapter "On the relations of nearly allied genera," he gives no less than eight "examples of exact parallelism." We select one at random as illustrating the large number of facts he brings to bear on the subject of which he treats. "The Cervidæ of the Old World are known to develop a basal snag of the antler at the third year; a majority of those of the New World never develop it, except in abnormal cases in the most vigorous maturity of the most Northern *Cariacus*: while the South American *Subulo* retains to adult age the simple horn of the second year of *Cervus*. Among the higher Cervidæ, *Rusa* and *Axis* never assume characters beyond an equivalent of the fourth year of *Cervus*. In *Dama*, on the other hand, the characters are assumed more rapidly than in *Cervus*; its third year corresponding to the fourth of the latter. Among American deer there is the *Blastocerus*, whose antlers are identical with those of the fourth year of *Cariacus*.

"Now, individuals of the genus *Cervus* of the second year do not belong to *Subulo*, because they have not as yet their mature dentition. *Rusa*, however, is identical with those *Cervi* whose dentition is complete before they gain the antlers of the fifth year. When the first trace of a snag appears on one beam of *Cariacus virginianus*, the

* "On the Origin of Genera." By Edward D. Cope, A.M., Corresponding Secretary of the Academy of Natural Sciences of Philadelphia. Pp. 80. 1869. (Philadelphia: Merrihew and Son. London: Trübner and Co.)

* The author applies the term *exact parallelism* to the relation of genera which are simply stems in one and the same line of development; while *incomplete parallelism* is applied to that of those where one or more characters intervene in the maturity of either the lower or higher genera to destroy identity.

dentition includes the full number, but there remain 3 milk molars much worn and ready to be shed. Perhaps the snag is developed before these are displaced. If so the *Cariacus* is never a *Subulo*; but there can be little doubt that the young *Blastocerus* belongs to that genus before its adult characters appear."

From the examples of inexact parallelism we select the second and eighth.

"In both perissodactylous and artiodactylous mammalia certain types develop their family character of canines at the earliest appearance of dentition; others, not till a comparatively late period of life (*Equus*); and the extreme genera never produce them" (p. 14).

"In most serpents the left lung is never developed; in such the pulmonary artery, instead of being totally wanting, remains as a posterior aorta bow, connected with the aorta by a ductus botalli; serpents without left lung being, therefore, identical in this respect with the embryonic type of those in which that lung exists."

Under the head of "adult metamorphoses," in the second chapter, Prof. Cope explains his law of retardation and acceleration. It consists "in a continual crowding backwards of the successive steps of individual development, so that the period of reproduction, while occurring periodically with the change of the year, falls later and later in the life-history of the species, conferring upon its offspring features in advance of those possessed by its predecessors. This progressive crowding back of stages is not, however, supposed to have progressed regularly. On the contrary, in the development of all animals, there are well-known periods when the most important transitions are accomplished in an incredibly short space of time (as the passage of man through the stages of the aorta bows and the production of limbs in the *Batrachia Anura*); while other transitions occupy long periods, and apparently little progress is made" (p. 37).

On these and other similar grounds, the author concludes, that "the transformation of genera may have been rapid and abrupt, and the intervening periods of persistency very long. As the development of the individual, so the development of the genus" (p. 38).

To the question—Has any such transition from genera to genera ever been seen to occur? Prof. Cope answers in the affirmative, and gives eleven probable and six ascertained cases, for the details of which we must refer to pp. 42–46.

Passing for want of space over the third and fourth chapters, we arrive at the concluding one, "On Epochal Relations, or those Measuring Geological Time," which abounds in valuable matter. The comparisons of different faunæ "indicate that an inherent difference between the types of a continent exists at the present time, though the difference is subordinated to a universal distribution of the higher groups throughout the earth. Has this state of things existed for any long period, or is it the result of different progress in the same group since the human period? Thus the present fauna of Australia was preceded in the post-pliocene and pliocene by forms possessing similar peculiarities, and belonging to the same classes: that is, by herbivorous and carnivorous marsupials and monotremes, and by *Varanid Sauria*, all of greater size than their predecessors.

"The same fact is well known of the Neotropical region,

its present peculiar *Edentata* having been preceded by giants of the same type in the post-pliocene and pliocene."

In the Nearctic, the later Palæarctic, and the Palæotropical regions, the existing genera were similarly represented by pre-existing types, sometimes wonderfully developed.

"Prior to these faunæ another state of things has, however existed. North America has witnessed a withdrawal of a Neotropical fauna, and the Palæarctic the retreat of an Ethiopian type. During the post-pliocene in North America, Neotropical genera were to Nearctic as 12 to 29, as the record now stands. In the pliocene beds of Pikermi (Greece) antelopes, giraffes, rhinoceros, hippopotamus, huge manis, monkeys, monitors, and other genera and species of African relationship, are the prevailing forms, and still earlier a strong mingling of Nearctic and more of Neotropical types abounded in the Palæarctic" (p. 77).

We have, then, three important terms from which to derive a theory of the creation:—(1) The existing six faunæ bear in many of their parts developmental relations to one another; (2) They were preceded immediately by faunæ similar to them in each case, but more remotely by faunæ like those now in existence; and (3) the Southern Hemisphere is a geologic stage behind the Northern one in progress, as is shown by its perfection in types extinct in the Northern, and by its inferiority in modern types prevalent in the Northern.

For a fuller demonstration of the last point we must refer our readers to pp. 78, 79 of this valuable monograph.

G. E. D.

MISS NIGHTINGALE ON LYING-IN INSTITUTIONS

Introductory Notes on Lying-in Institutions. By Florence Nightingale. Pp. 110. (Longmans, Green, and Co. 1871.)

MISS NIGHTINGALE tells us the story of this book somewhat as follows:—The Committee of the Nightingale Fund, with the view of extending the usefulness of their Institution for training nurses, entered into an arrangement with St. John's House and King's College Hospital, by which a special ward was set apart for the reception of poor women in childbed, and steps were taken for training midwifery nurses to be employed among the poor in their own houses.

After the ward had been in use for several years, the Committee were made aware that there had been many deaths among cases admitted; this led to inquiry, and the ward was closed.

The Committee being still desirous of continuing this special branch of their work, Miss Nightingale deemed it advisable to inquire into the whole subject of puerperal mortality, and the result is now before us in a form which we can all understand, and we will venture to say that to the generality of readers the facts will bear the aspect of an unwelcome revelation. These facts have been drawn from the Registrar-General's reports, from reports of public institutions in the United Kingdom and over most European countries, affording relief to poor women in their need, both at home and in lying-in institutions, and also from records of private practice.

They show that, while the death-rates for all England

from diseases and accidents peculiar to childbirth amount to 4·83 per 1,000, they exceed this amount whenever women pass within the walls of lying-in hospitals—increasing to 5, 6, 7, and in one instance to above 19 per 1,000. If we confine our attention to puerperal diseases, we find that, while the death-rate for all England from these is 1·61 per 1,000, it mounts up in workhouses and other lying-in establishments to 3·3, 3·9, 4·1, and 14·3 per 1,000. In King's College Hospital lying-in ward, the puerperal disease death-rate was nearly 29½ per 1,000. By using Dr. Lefort's data, which give the death-rates from all causes at home and in hospital, in various European countries, it is shown that the approximate death-rate at home is 4·7 per 1,000, while in lying-in institutions it is no less than 34 per 1,000.

Miss Nightingale discusses the causes of these immense death-rates, which, she reminds us, occur among women undergoing not a diseased, but a perfectly natural condition, among whom a death "is little short of a calamity," and "almost a subject for an inquest." We cannot enter into the discussion, but we can say distinctly what is the impression produced by the evidence. It affords another illustration of the danger of unenlightened philanthropy. Some one takes pity on poor suffering women, and forthwith builds an hospital for them or gets it built, without a thought, apparently, of what organic laws of human nature he is about to violate. Nature takes no account of his good intentions, but just goes on, as Miss Nightingale has elsewhere said, "to levy her own cess in her own way."

The practical result of the whole discussion is that lying-in establishments, as at present managed, are destructive of human life, and should be forthwith closed, and that poor women should, as a rule, be attended at home.

The case, however, is not altogether hopeless; and Miss Nightingale proceeds to show how an institution for training midwives and midwifery nurses can be planned and managed without risk. The whole secret consists in assimilating the establishment to home conditions, whatever the cost may be. The evidence shows that in such an institution there would be no more risk than at home. The difficulty, as it appears to us, would be in the cost and in the perfection of management required, which could only be attained by persons practically conversant with physiological laws. But, at the same time, there can be no question of the superior advantages for training which such an institution would afford. This portion of the book is illustrated by plans of existing hospitals, and of the proposed training school. It contains a large amount of valuable detail in small compass, well worthy the attention of the medical profession and the public at large; concluding with an appeal to women, desirous of entering on medical studies, to make this department of practice their own.

The book, as its title implies, is tentative, and there is prefixed to it a quaint dedication to "the shade of Socrates' mother," including a call for help to "the questioning shade of her son, that I, who write, may have the spirit of questioning aright, and that those who read may learn not of me but of themselves." If this Socratic spirit of "questioning aright" were more cultivated, we should have fewer philanthropic mistakes, and science would be less troubled than it has been of late by dogmatic assertions and crude speculations.

OUR BOOK SHELF

Text-Book of Geometry. Part I. By T. S. Aldis, M.A., Senior Mathematical Master, Manchester Grammar School. (Deighton, Bell, and Co.)

WE are much pleased with this book as a good text-book for teaching geometry. It is evidently the work of one who has been at the pains to consider well what are the difficulties which the average pupil encounters. It is the work, too, of one who has seen what the fault of the school teaching of geometry has hitherto been, and who is determined, as far as lies in his power, to remedy it. The evil of school-teaching has been that Euclid has been learned by rote, or when things have not been so bad as that, its propositions have been regarded too much as only abstract truths, which neither have been elucidated by, nor have been used to elucidate natural phenomena or the ordinary things of life. Mr. Aldis supplies this defect by an admirable series of examples and exercises appended to each proposition, calculated to give a practical turn to the whole study in the mind of a beginner, and to familiarise him early with the idea that he can really make use of the subject, and can give it a vast variety of application. Mr. Aldis frequently gives more than one demonstration of the same proposition. This also is very useful in teaching, inasmuch as it practically informs the pupil that the truths of geometry are independent of any particular demonstration of them, and gets him into the habit of approaching any problem from more than one point of view. The present is a first instalment. It contains pretty nearly what is in Euclid's first four books. J. S.

Populäre Wissenschaftliche Vorträge. Von H. Helmholtz. 2tes Heft. (Braunschweig: Verlag von F. Vieweg. London: Williams and Norgate.)

THIS part of Helmholtz's essays reminds us in many respects of Tyndall's lectures—in their clear and eloquent language, eminently adapted for popular comprehension, their freedom from technical expressions, except where these are unavoidable, and in the original mode in which well-known facts are dealt with and used to illustrate profound scientific truths. The work contains six lectures, of which three are devoted to recent advances in the theory of vision, one to the correlation of the physical forces, one to the conservation of force, and the last to the objects and advances of science. In the three lectures devoted to the eye, whilst extolling its perfection as an instrument in the mode in which we use it, he points out its various defects; the blind spot, the blind lines and strice corresponding to the vessels, its incapacity to focus equally red and violet rays, the want of uniformity in its refraction as indicated by the lines that appear to proceed from a star, &c. He discusses the various colours of the spectrum, and represents this not in the mode usually adopted of a circle with segments of various sizes corresponding to the several primary colours, but as a triangle, of which green, violet, and red occupy the angles, and blue, yellow, and purple the sides, white having an eccentric position near the yellow. Violet, which he was formerly disposed to regard as a primary colour, he again admits, and he seems inclined to advocate, as best explaining the phenomena of colour-blindness, the views of Young: that there are special nerves for perceiving red, green, and violet rays, an opinion that is less surprising in view of Brown Sequard's conclusions in regard to the number of channels for special sensations contained in the spinal cord, and which is also supported by the remarkable specialisation shown by Helmholtz himself to occur in the branches of the auditory nerve indicated by the phenomena of certain defects of hearing. The chapters on the correlation of the physical forces and the conservation of force, subjects that are now familiar to most scientific Englishmen, are very interesting, as being, to use the German phrase, amongst the original path-breaking essays on these subjects. H. P.

Notes on the Food of Plants. By Cuthbert C. Grundy, F.C.S. (London: Simpkin, Marshall, and Co., 1871.)

THIS is a useful elementary sketch of the form and manner in which food is obtained by plants. Faults in it there are. Thus, notwithstanding the conclusive experiments of Prillieux and Duchartre, proving that plants have no power of absorbing moisture through their leaves, and the author's own reference to this now established fact in the preface, we still find the assertion (p. 14) that "the leaves withdraw from the atmosphere aqueous vapour." The statement (p. 25) that the sap descends in dicotyledonous plants *through* the bark is not strictly correct; and a Fellow of the Chemical Society ought not to have described (p. 23) carbonic acid as "carbon dioxide combined with water." These blemishes apart, this little book may be recommended to those who desire an explanation of the mode in which vegetable organisms are built up from inorganic materials, and who are unable to devote the time to the more elaborate works of Mr. Johnson, "How Crops Grow" and "How Crops Feed." The portion relating to the effect on crops of different soils strikes us as the best.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Proof of Napier's Rules

As the following graphical construction is easily executed, representing to the eye the figure usually employed for the proof of Napier's rules of the parts of right-angled triangles in spherical geometry, it will perhaps remove difficulties from their proof for beginners, like those which Mr. W. D. Cooley's work on "Elementary Geometry" must, from his description of some interesting parts of its contents in *NATURE* of the 19th of October, have proposed to itself to meet, and to render at least as easily accessible as possible to the inquiring student in mathematics.

BF is a rectangular card, measuring two inches by three inches in the sides, and divided by the lines DB, DC, DA, DB', and B'C in the directions shown in the figure, and in such a manner that the three corners of the rectangle are completely cut away by the last two, and by the first of these lines; while DC and DA are only cut or scored lightly in the card, so as to allow the remaining three triangles, DBC, DCA, DAB', to be folded towards each other, until, DB and DB' coinciding, they form a solid angle of three faces at the point D. The property possessed by this solid angle, that the inclination of the two faces, DCB, DCA, to each other is a right angle (the angle shown at C' in the base, AB'C' of the solid angle), and that the base AB'C' of the resulting tetrahedron cuts the two faces ADC, ADB', perpendicularly (or at right angles to their common intersection DA) in the line AC, AB', so that the plane angle A of the plane right-angle triangle B'AC' is also the inclination between those faces, or $t.c.$

angle of the right-angled spherical triangle formed by the intersection of a sphere, about the centre D, with the three planes meeting each other at that point, affords a ready proof of all Napier's rules, excepting that connecting the two angles of a right-angled spherical triangle, from the simple definitions of the trigonometrical "ratios" of plane angles.*

Calling the angles of the faces which meet together at the point D, as shown in the figure a, b, c , opposite to the spherical angles A, B, C, formed by the inclination of the other two faces to each other, these angles, and those of inclination of the faces are, respectively, the sides and angles of a right-angled spherical triangle, whose right angle is C, its hypotenuse is c , and the angle A, between b and c is equal to the plane angle A, of the right-angled triangle AB'C'.

Taking, firstly, as the radius, DA, equal to unity, AC (or AC'), and AB' are the tangents of b and c ; and the right-angled triangle AC'B' gives the rule,

$$\frac{\tan b}{\tan c} = \cos A; \text{ or } \cos A = \tan b \cdot \cot c \quad (1)$$

Taking, in the next place, DB, (or BB'), as the radius, equal to unity; BC (or B'C'), and B'A are the sines; and DC, DA are the cosines of the angles a and c . In the first case the right-angled triangle ABC' affords the ratio

$$\frac{\sin a}{\sin c} = \sin A; \text{ or } \sin a = \sin c \cdot \sin A; \quad (2)$$

And in the second case we obtain from the right-angled triangle ADC the rule

$$\cos c = \cos a \cdot \cos b \quad (3)$$

The rules for the angle B, corresponding to (1) and (2) for the angle A, are simply obtained from them by transposing in them the sides and angles a for b B; thus—

$$\cos B = \tan a \cdot \cot c \quad (4)$$

$$\sin b = \sin c \cdot \sin B \quad (5)$$

Finally, dividing (1) by (5), a rule for connecting together the two angles of the right-angled spherical triangle is found as follows:—

$$\cos a \div \sin b = \frac{\tan b \div \sin b}{\tan c \div \sin c} = \frac{\cos c}{\cos b} = \cos a, \text{ by (3);}$$

$$\text{or } \cos a = \cos a \sin B \quad (6)$$

If, as in Napier's rules, the two sides and the differences from 90° of the two angles and of the hypotenuse arranged in their natural order round the triangle are regarded as constituting its five parts, it will be seen that all the above consequences may be included in the two rules known as Napier's rules, that the sine of the middle (that is, of any chosen) part is equal to the product of the tangents of the two adjacent, as well as to the product of the cosines of the two opposite parts.

As a rule to assist the memory, the laconic brevity and completeness of Napier's formula possess a most uniquely felicitous, and, happily for mathematicians, a not unfrequently enduring charm. But should the student desire to divest himself of their artificiality, and to retrace for himself the steps of the demonstration upon which any one example of these rules is based, he must first draw a solid tetrahedron ABCD, in which the facial angles at A, C, are as represented in the figure, but as they cannot all be correctly shown on account of the embarrassing effects of the perspective in the drawing, right angles. By having recourse to a model, on the other hand, which may very readily be cut from a card like that illustrated in the above description, and folded so as to form the solid figure required for their demonstration, all the cases of Napier's rules may be exhibited, and proved, almost as speedily, and satisfactorily to a learner's apprehension in solid geometry, as the definitions of the simple trigonometrical ratios of plane angles, and the least complicated relations connecting together the parts of plane triangles may be made intelligible to him; and that by a plain series of immediate deductions from the figure, which his familiarity with the processes of plane trigonometry will already have taught him very easily to supply.

Newcastle-on-Tyne, Oct. 30

A. S. HERSCHEL

Remarkable Paraselen seen at Highfield House on October 25th, 1871

THE phenomenon first became visible at 7h 12^m P.M., and finally vanished at 7h 33 P.M. The upper portion of a halo of

* Another similar property, with a somewhat less important application of the same tetrahedron, is described in the *Quarterly Journal of Mathematics* for October 1862, p. 306.

$22^{\circ} 30'$ radius marked DCE, together with a detached portion of F, had the moon for its centre; at the apex of this circle was the apex of another of similar dimensions, HCG, whose centre was about $45'$ al' ove the moon. On the horizontal level of the moon on either side were mock moons, AB, and immediately above the moon within the same circle was an oval mock moon, C.

Both A and C, though very apparent, were nevertheless not brilliant, the grandeur of the phenomenon centering in the double mock moon B; this was so brilliant that it attracted immediate attention, and that portion nearest the moon was sensibly orange-red. At first it appeared as one large rock moon (twice as broad as it was long), and at $7^h 19^m$ divided into two with a thin dark band between. While the two moons (touching each other) were visible, each had a tail of 10° or more in length, and these were included within a gigantic tail of 25° long, considerably more brilliant, but colourless, and contrasting much with the orange-red of the mock moons. At the time of the phenomenon a fog spread over the valley, and overhead were strong cirri in parallel bands. The temperature was $37^{\circ} \cdot 2$, and on the grass $36^{\circ} 6$.

The moon shone brightly and the sky was cloudless near her throughout the whole time. At $7^h 33^m$ a cloud of considerable density obscured both the moon and the phenomenon.

E. J. LOWE

Structure of *Lepidodendron*

I MAY, perhaps, notwithstanding the editorial injunction to the contrary, be permitted to make one remark by way of addition to what I said in my last letter on this subject. I have been favoured by Mr. J. T. Young with the inspection of some *Lepidodendroid* stems from the Lancashire coal-fields. These are somewhat different from any others which I have seen, and are probably similar to those Prof. Williamson is working with. At any rate they enable me to understand, what otherwise I have failed to comprehend, namely, the three structures which Prof. Williamson sees in the vascular axis of these plants. In Mr. Young's specimens a transverse section of the vascular axis exhibits (1) the investing cylinder, (2) a zone of larger scalariform vessels, (3) a central irregular mass of vertically disposed rows of scalariform cells with transversely truncate ends. Suppose the transverse septa separating these cells absorbed, as probably eventually they would have been, and the rows of cells become scalariform vessels. I see no reason therefore to lead me to alter my views upon this matter, or to look upon 2 and 3 as forming more than one central structure distinct from 1, the investing cylinder.

W. T. THISELTON DYER

Is Blue a Primary Colour?

No exception can be taken against Dr. Aitken's argument in your number for Oct. 12. The colours of the substances he experimented on could not be regarded as simple. But he does not consider how loosely all names of colours must be applied in common language. The colours of most blue pigments, especially in thin washes, no doubt contain a large proportion of green. But let the colour of the blue saliva, or that of the pigment called French blue or ultramarine (often given as the best example of true blue) be tested in conjunction with the purest yellows (even with the almost greenish yellow of the pigment called lemon-yellow) and the two will be found perfectly complementary. This is the colour of Newton's indigo rays, which he himself in his colour circle put opposite to his yellow. In fact, in good English, not only sea-greenish blues, like the colour of Newton's blue part of the spectrum, or that of the pigment called azure or *caeruleum*, but even the colour of the violet itself, is properly called blue. Witness Milton's "beds of violets blue." The violet of the spectrum is in truth little more than a pure blue diluted with white by reason of the fluorescence of the retina, as recent researches have shown. (See J. J. Müller's paper in *Poggendorff's Annalen*, March and April last.) I must, therefore, protest against substituting a fanciful term like violet for the good English blue, as the designation of a simple colour-sensation. It is hard enough to make artists believe that yellow is not a simple colour. To tell them the same of its complementary blue would add to their disgust, and not unreasonably.

WILLIAM BENSON

MR. AITKEN in his letter in NATURE, Oct. 12, seems to find primary with pure colours; it is true they are pure in a certain sense, but in what sense is fully explained in Prof. J. C. Maxwell's lecture, given in NATURE, vol. iv. p. 13. All the experiments mentioned by Mr. Aitken merely prove that the blue colours we commonly see are mixed ones; but the same is the case with almost all the colours we see, while any tint of the spectrum, whether primary or not, may be had pure, i.e., consisting of homogeneous light. Likewise colours which appear just the same to the eye may be made of very different components.

T. W. BACKHOUSE

A Shadow on the Sky

ON the 21st of last August, being at Zermatt, Switzerland, I witnessed from the balcony of the *salle-a-manger* of the Hotel du Mont Cervin a very remarkable appearance. The sun had recently set, and, as I was intensely enjoying the view of that extraordinary mountain, the Matterhorn, I saw its shadow thrown upon the clear sky in the most distinct manner. It was the exact figure of a cone lying obliquely, with its apex somewhat in an upward direction, and its base taking its origin from the S.E. side of the mountain. The cone was well defined, the edges of the shadow being sharp and regular. The moon was, from our point of view, at this time behind the Matterhorn. I immediately acquainted some gentlemen, who were at supper in the *salle-a-manger*, with this interesting appearance, and all were much struck with it. My son, Marshall Hall, had just retired to rest, having to be up at two the next morning, in order to make a new ascent in this locality; but I called him out into the garden to enjoy with me this striking scene. The deep, distinct shadow added to the weird effect always produced by this extraordinary mountain, and it so impressed me that I thought the phenomenon might be worth recording in your journal.

Brighton, Oct. 23

CHARLOTTE HALL

A Plane's Position

THIS question is becoming one *de gustibus*, and its further discussion will probably be profitless. I retain my opinion, and am content with the few who side with me. In the two finest treatises on astronomy published during the present century, Herschel's "Outlines of Astronomy," and Grant's "History of Physical Astronomy," the word position is used as I use it. Not systematically, I admit; for Herschel sometimes wrote "situation" where I should write "position." Grant in one place deals somewhat definitively with the word, for at p. 258 he writes, "The position of Saturn's ring is usually determined by the inclination of its plane to the ecliptic and the longitude of its ascending node," the longitude of this node being defined,

as all astronomers know, by the *direction* of the line of nodes, not by its *actual place*.

By-the-by, Sir John Herschel is sometimes very careful to use the words "actual place" where my critics contend that the word "position" would be sufficiently definitive.

It seems overlooked that I pointed out in the beginning that "position" was often but erroneously used as synonymous with "place." It is not my fault if this error appears in the technical use of the word "position" in some mathematical treatises. I say again with Colonel Manning, *Abusus non tollit usum*—"The abuse of anything does not abrogate the lawful use thereof." It was a *lapsus calami* of mine to say that "position" could not be misunderstood. It could be, for it has been misused.

Prof. Hirst is quite right in saying I should be unable to describe the place of a horizontal plane. I should not think of trying to. He says, however, that Mr. Wilson would unhesitatingly pronounce its aspect *vertical*. (Does it look vertically *up* or vertically *down*?) What would Mr. Wilson assign—unhesitatingly or otherwise—as the aspect of the "prime vertical"?

Has a true plane (as distinguished from a plane face of a solid) one aspect or two? It has one *position* or *situation*, and one *place* or *location*, but I conceive that it has two aspects.

Mr. Laughton seems quite unaware of Sir J. Herschel's repeated use of the word "tilt."

His comment on my remark about the books which I have written is unworthy. He must surely perceive that I only sought to indicate how much occasion I had had to consider the subject of plane-position; more occasion, I think, than any of my critics, save Prof. Hirst, the weight of whose opinion I recognise fully, though I cannot agree with him. But I have not felt free to use the word "position" so systematically as I should wish, precisely because of its misuse to indicate *place*. I have only been able to use it where there could be no fear of that wrong meaning being assigned to it.

As I claim no credit for the invention of any word for indicating plane-position, and as I could not take from Mr. Laughton that which is not his—the credit for Hamilton's word "aspect"—perhaps I may be permitted to say that if I am "pertinacious" (as Mr. Laughton asserts) there is nothing personal in my pertinacity. It is not my custom to admit that I am wrong when I consider that I am right.

[My objections to the word "aspect" are confirmed by Mr. Wilson's letter. I wrote that the word could not be used in the sense indicated, "unless a new and artificial meaning were assigned to it." Mr. Wilson obligingly proves this by assigning to it just such a meaning. "The aspect of a plane is the direction of its normal," it would seem. Now no special objection need be urged against this definition, if it is to be confined rigidly within the limits of mathematical text-books. The definition is strange and artificial no doubt; but it is nothing new to see the familiar and natural banished from such works. As a writer on astronomy, however, I must decline to accept the proposed usage, which seems to me altogether objectionable. If I write respecting the celestial equator-plane that "its position is at right angles to the polar axis of the heavens," I find that I am unde stood; but I am sure my readers would be very much perplexed if I wrote that "the aspect of the equator-plane is the direction of the polar axis." Again, I should be understood, I think, if I said that "the positions of two hour-planes determine the direction of the polar axis," or that "the directions of the polar axis and the vertical determine the position of the meridian-plane." But if I write "aspect" where I have here written "position," I scarcely know what my readers would think.

By the way, what would be the "aspect" of the meridian-plane according to the proposed usage? Would it be "east" or "west"? The normal to that plane would lie east and west; but we could not hear of an "east-and-west" aspect without thinking of certain "clear stories towards the south-north, lustrous as ebony."

I am bound to point out, however, though I may seem to weaken my position by doing so, that a very eminent authority long since used the word "aspect" in the sense suggested by Mr. Laughton. In one of his well-known "Letters to a Lady," on quaternions, Sir W. R. Hamilton uses the words "position," "slope," "ledge," and "aspect," to express the relations which I have called respectively "place," "slope," "aspect," and "position." (See Nichol's "Cyclopædia of the Physical Sciences," 2nd edition, p. 705.) I app end, however, that he lays no special stress on this verbage. He had used the word "position" for "place," and this left him without any word to indicate position. Besides, his illustrative plane is the surface of

a desk, and a surface may be conceived to have an aspect definable by the direction of its normal, but a geometrical plane is two-faced.]

This is my last letter on the present subject—unless one of your correspondents should employ arguments showing me to be in error, in which case I shall crave two lines of your space to admit as much.

RICHD. A. PROCTOR

Brighton, Nov. 3

P.S.—Let it be noticed that the question is not how the word "position" has been used by some, but how it ought to be used by all.

I CANNOT agree with Mr. Wilson that "aspect" is *exactly* the word wanted. The same wall has *two* aspects; if a southern, then also a northern aspect on the other side. In fact the word seems adapted, according to its common usage, to express the "sense" (*sens*), as well as the direction of the plane's normal, whereas I take it that the word sought for should express the direction only without connoting the "sense."

I think a word sometimes used by geologists would be, if we dare use it, exactly the word. As they speak of the *lie* of strata, defined (with respect to the horizon) by its two elements, *strike* and *dip*, so geometers might well speak of the *lie* of a plane; but would our English language permit us to say that "two lies determine one direction," and "two directions determine one lie"? I fear the moral connotation of the word, although an etymological accident, is too ugly.

If we are reduced to coin a new word, I would suggest that the Latin root "pand" (spread), would afford for a plane the fitting analogue of the root "reg" (rule, make straight), for a line, and so the word "dispansion" would be the analogue of "direction." "Parallel planes have the same dispersion." "Two dispansions determine one direction, and two directions determine one dispersion." Will not the neatness of this mode of expressing Mr. Wilson's test propositions atone for the strangeness of the word?

The word "aspect," however, is too good to be rejected from geometrical science, though I believe its chief use will be found beyond the domain of pure geometry. Should it not be appropriated to cases where the plane presents different aspects to the portions of space on either side of it? For instance, if two bodies revolve in the same or parallel planes, their orbits might be said to have the same or contrary aspects, according as the bodies revolve in the same or contrary directions, and so the positive aspect of a planet's orbit would determine, not only the "lie" or "dispansion" of the plane of the orbit, but also the direction of revolution in that orbit. So, too, the statement that all the planetary orbits have nearly the same aspect, would imply not only that their planes nearly coincide, but also that they all revolve in the same direction. I cannot help thinking that Mr. Proctor would find his account in adopting this sense of the word "aspect" in his astronomical writings, especially since he might, as Dr. Hirst suggests, retain the word where he has hitherto employed it, by simply qualifying it with an appropriate adjective. (Would the adjective "azimuthal" satisfy him?)

May I conclude with a question which I have often wished to propound? What is the proper English equivalent for the French "*sens*"? English mathematicians generally seem shy of using the word "sense," while, to use the word "direction" as well for the "*sens*" as the "direction" of a line, is very awkward and inconvenient. The difficulty, I imagine, is the same as appears to me almost fatal to the word "lie" proposed above, namely, that the proposed technical use diverges too widely from the familiar use of the word. Is not the superior flexibility of the German language in the formation of new terms in part due to a less degree of fastidiousness in this respect?

Harrow, Nov. 6

ROBT. B. HAYWARD

AFTER all, I fear the word "aspect" is not quite the right thing. What is wanted is a word to express "plane-direction," something in the plane, and not looking out from it. And I am not sure that the compound word "plane-direction," which is not ambiguous nor colloquial, will not be better even than "aspect."

We should then have axioms on planes analogous to those on straight lines: that planes may have the same or different plane-directions; that intersecting planes have different plane-directions; and conversely.

Parallel planes will be defined as those which have the same plane-direction.

* The matter between brackets was written on October 27.—ED.

With this word it is easier to state the theorems, "two line-directions determine one plane-direction," and its reciprocal, than with the other. "Two directions determine one aspect," is hard.

If this discussion has not gone on too long perhaps some of your correspondents will criticise this suggestion and compare it with "aspect." It is desirable that the best word possible should be chosen.

J. M. W.

Science and Art Examinations

THE subject of Science and Art Examinations by the Department of Science and Art is one which really requires looking up, and I wish to make one or two suggestions and remarks as to the mode of examination.

In the first place, take the examination itself. The candidates make their appearance at the appointed time and place. Their forms are given them, and their places assigned to them. Now the candidate is told to write on both sides of the form, thus leaving no back pages on which to do his rough calculation. Blotting-paper in 1870 was not allowed; but in 1871 the Department fixed a sheet to the bottom of each form in such a position that it was very difficult to make use of it; much time—time that was of the utmost consequence to the candidate—being lost in doing so. This, of course, stopped him from doing so much work, and so lessened his chance of success. This may be all very well for the Department so far as it affects grants on results; but what about the unfortunate student who is made the victim of this very arbitrary custom?

Then again for the questions set. In all the papers the questions set were very difficult. "The Department" having, without any notice, raised the standard of examination, the subjects of questions set in the first stage of mathematics were placed in the syllabus a stage higher, viz., the second stage. Then in chemistry (inorganic) the standard was considerably raised. The questions in this subject are very unfair in the opinion of many persons who have seen them. Take the following:—

"HONOURS 1871"

"Describe the process of manufacturing sulphuric acid, as carried on in an alkali works, illustrating the various chemical changes by equations, and, as far as possible, the constitution of the compounds formed by graphic formulæ."

Now about the sulphuric acid part, or about the equations, I have nothing to say; but when the question requires a knowledge of graphic formulæ I protest against it. Graphic formulæ are not in sufficient use to warrant their introduction into an examination—thus enforcing their general adoption whether right or wrong; and I do not think the examiner should be allowed to enforce his peculiar views—the views taken by himself and a few other chemists—into the great system of Science examination in the country, thus compelling it to be learnt by any person wishing to compete.

Now for the results. The results of the examinations for 1871 are very unsatisfactory, and a very high ratio is shown of failures, and second classes to first classes obtained. This, of course, must lessen the amount of money to be paid on results by the Department, and a report was circulating a short time ago, to the effect that "The examiners, after having made their reports, had the papers returned to them, with an instruction to reduce the number of successful candidates, as an intimation had been given by a right hon. gentleman that the amount of grant due upon those papers must be reduced 20,000*l*." The examiners were thus obliged to eliminate half the names from their lists." The question was asked by Mr. Dixon, M.P., in the House of Commons, whether this was or was not true, and Mr. Forster, M.P., denied it. But, previous to that, a provincial local secretary, hearing the rumour, wrote to ask the Department if it were true, and received a reply saying it was true, and that instead of the amount being 20,000*l*, it was 40,000*l*. (The Department's letter can be produced.) Now I would suggest that the Department reform these matters referring to the forms, blotting-paper, questions, and results, and that if they do not do so that the House of Commons take the matter up and do justice to Science teachers and students.

HENRY UHLGREN

New Zealand Forest Trees

IN the last number of NATURE is a paragraph relating to some New Zealand woods, which the writer observes are "deserving of

a better fate than to be cut down wholesale and used as firewood." Five timber trees are mentioned, of which the native names only are given.

Knowing that it is the province of NATURE to give as accurate information as possible on all points with which it deals, I send you the botanical names of four of these New Zealand trees. The Rimu or red pine is probably *Dacrydium cupressinum* Soland., a tree 83 or more feet high, the fleshy cup of the fruit of which is eatable. *D. laxifolium* Ilk. fil., a small creeping bush, is also known occasionally as Rimu. The Matai or black pine is *Podocarpus spicata* Br., likewise a large tree, and having an eatable fruit. The Totara is *Podocarpus totara* A. Cunn., a tree about 60 feet high, producing a durable and close-grained wood much valued in the islands, and, like the others, having an eatable drupe. These trees are all more or less abundant in the Northern and Middle islands, and all belong to the natural order Coniferae, though we are told in the paragraph referred to that "none of them are Coniferae."

The Kata, "that wonderful vegetable production forming itself out of numberless vines," &c., is referable to some species of *Metrosideros*. *M. robusta* A. Cunn. and *M. florida* Sm., are both known as Kata, but the hard and very dense wood usually known under that name is mostly derived from *M. robusta*. This, however, is not a climbing plant, but an erect tree 50 or 60 feet high; therefore the plant referred to in the paragraph before us is probably *M. florida*. The Makia I do not know, but its extreme hardness would seem to indicate it as belonging to the same order as the last, namely the Myrtaceae.

JOHN R. JACKSON

Kew, Nov. 7

The Glacial Drift at Finchley

A FURTHER examination of the railway cutting at the Finchley and Hendon Station shows that the glacial beds now revealed there have a greater thickness and range than I at first imagined. On Saturday last I visited the place in company with Dr. Hicks, of Hendon, a gentleman well-known for his researches in the Cambrian formation. Above the blue clay, and right up within a few inches of the vegetable soil, we found drift fossils. With an interruption here and there from the underlying London clay, these chalky glacial beds, consisting of blue (Oxford?) clay, blueish clay with flints, marl, sand, and gravel (in no regular descending order), have an average thickness of 30 feet. They are open for about 500 yards, and they might perhaps be traced farther north-west, towards the Dollis Brook Viaduct. Dr. Hicks and I afterwards visited Mr. Plowman's Manor brick-fields, a little south-east of the railway station; here too we found fossils in the brick-earth.

From what has transpired during the last few weeks, it would seem that the Muswell Hill deposit need no longer figure in geological literature as an outlier, at a long distance from the general deposit; and Londoners may in future find glacial drift without much difficulty about Highgate, Finchley, Whetstone, and Barnet. I am indebted to Professor Morris for the information that the Great Northern Cemetery at Barnet lies almost wholly in the glacial clay. The forthcoming Survey memoir upon the drift in this district is looked for by London geologists with much interest.

HENRY WALKER

100, Fleet Street, E.C., Nov. 7

ON THE ORIGIN OF INSECTS*

THE metamorphoses of this group have always seemed to me one of the greatest difficulties of the Darwinian theory. In most cases the development of the individual reproduces to a certain extent that of the race, but the motionless, imbecile, pupa cannot represent a mature form. Fritz Müller considers that the wingless Blatidæ probably most closely represent the original insect stock; Haeckel is inclined rather to the Pseudo-Neuroptera. I feel great difficulty in conceiving by what natural process an insect with a suctorial mouth like that

* Abstract of a paper read before the Linnean Society, Nov. 2, 1871, by Sir John Lubbock, Bart., M.P., F.R.S.

of a gnat or butterfly could be developed from a powerfully mandibulate type like the Orthoptera, or even from the Neuroptera. M. Brauer has recently suggested that the interesting genus *Campodea* is, of all known existing forms, that which probably most nearly resembles the parent insect stock. He considers that the grub form of larva is a retrograde type, in which opinion I am unable to concur, though disposed to agree with M. Brauer on the first point. M. Brauer in coming to this conclusion relies partly on geological considerations; partly on the fact that larvae, more or less resembling *Campodea*, are found among widely different groups of insects. I think there are other considerations which offer considerable support to this view. No one, so far as I know, has yet attempted to explain, in accordance with Mr. Darwin's views, such a life history as that, for instance, of a butterfly, in which the mouth is first mandibulate and then suctorial. A clue to the difficulty might, I think, be found in the distinction between developmental and adaptive changes, to which I called the attention of the Society in a previous memoir. The larvae of insects are by no means mere stages in the development of the perfect animal. On the contrary, they are subject to the influence of Natural Selection, and undergo changes which have reference entirely to their own requirements and condition. It is evident then that, while the embryonic development of an animal in the egg gives us an epitome of its specific history, this is by no means the case with species in which the immature forms have a separate and independent existence. Hence, if an animal when young pursues one mode of life, and lives on one kind of food, and subsequently, either from its own growth in size and strength, or from any change of season, alters its habits or food, however slightly, immediately it becomes subject to the action of distinct forces; Natural Selection affects it in two different, and it may be very distinct, manners, gradually leading to differences which may become so great as to involve an intermediate period of change and quiescence.

There are, however, peculiar difficulties in those cases in which, as among the Lepidoptera, the same species is mandibulate as a larva and suctorial as an imago. From this point of view, however, *Campodea* and the *Collembola* (*Podura*, &c.) are peculiarly interesting. There are among insects three principal types of mouth, firstly, the mandibulate, secondly, the suctorial, and thirdly, that of *Campodea*, and the *Collembola* generally, in which the mandibles and maxillæ are attached internally, and though far from strong, have some freedom of motion, and can be used for biting and chewing soft substances. This type is intermediate between the other two. Assuming that certain representatives of such a type found themselves in circumstances which made a suctorial mouth advantageous, those individuals would be favoured by Natural Selection in which the mandibles and maxillæ were best calculated to pierce or prick, and their power of lateral motion would tend to fall into abeyance, while, on the other hand, if powerful masticatory jaws were an advantage, the opposite process would take place.

There is yet a third possibility—namely, that during the first portion of life the power of mastication should be an advantage, and during the second that of suction, or *vice versa*. A certain kind of food might abound at one season and fall at another; might be suitable for the animal at one age and not at another: now in such cases we should have two forces acting successively on each individual, and tending to modify the organisation of the mouth in different directions. It will not be denied that the ten thousand variations in the mouth parts of insects have special reference to the mode of life, and are of some advantage to the species in which they occur. Hence no believer in Natural Selection can doubt the possibility of the three cases above suggested, and the last of which seems to explain the possible origin of species which are

mandibulate in one period of life and not in another. The change from the one condition to the other would no doubt take place contemporaneously with a change of skin. At such times we know that, even when there is no change of form, the temporary softness of the organs often precludes the insect from feeding for a time, as, for instance, is the case in the silkworm. When, however, any considerable change was involved, this period of fasting would be prolonged, and would lead to the existence of a third condition, that of pupa, intermediate between the other two. Since other changes are more conspicuous than those relating to the mouth, we are apt to associate the pupa state with the acquisition of wings, but the case of the Orthoptera (grasshoppers, &c.) is sufficient proof that the development of wings is perfectly compatible with continuous activity. So that in reality the necessity for rest is much more intimately connected with the change in the constitution of the mouth, although in many cases no doubt the result is accompanied by changes in the legs, and in the internal organisation. It is, however, obvious that a mouth like that of a beetle could not be modified into a suctorial organ like that of a bug or a gnat, because the intermediate stages would necessarily be injurious. Neither, on the other hand, for the same reason could the mouth of the Hemiptera be modified into a mandibulate type like that of the Coleoptera. But in *Campodea* and the *Collembola* we have a type of animal closely resembling certain larvae which occur both in the mandibulate and suctorial series of insects, and which possesses a mouth neither distinctly mandibulate nor distinctly suctorial, but constituted on a peculiar type capable of modification in either direction by gradual changes without loss of utility.

If these views are correct, the genus *Campodea* must be regarded as a form of remarkable interest, since it is the living representative of a primeval type from which not only the *Collembola* and *Thysanura* but the other great orders of insects have all derived their origin.

CHARLES BABBAGE

DIED THE 20TH OF OCTOBER, 1871

THERE is no fear that the worth of the late Charles Babbage will be over-estimated by this or any generation. To the majority of people he was little known except as an irritable and eccentric person, possessed by a strange idea of a calculating machine, which he failed to carry to completion. Only those who have carefully studied a number of his writings can adequately conceive the nobility of his nature and the depth of his genius. To deny that there were deficiencies in his character, which much diminished the value of his labours, would be useless, for they were readily apparent in every part of his life. The powers of mind possessed by Mr. Babbage, if used with judgment and persistence upon a limited range of subjects, must have placed him among the few greatest men who can create new methods or reform whole branches of knowledge. Unfortunately the works of Babbage are strangely fragmentary. It has been stated in the daily press that he wrote eighty volumes; but most of the eighty publications are short papers, often only a few pages in length, published in the transactions of learned societies. Those to which we can apply the name of books, such as "The Ninth Bridgewater Treatise," "The Reflections on the Decline of Science," or "The Account of the Exposition of 1851," are generally incomplete sketches, on which but little care could have been expended. We have, in fact, mere samples of what he could do. He was essentially one who began and did not complete. He sowed ideas, the fruit of which has been reaped by men less able but of more thrifty mental habits.

It was not time that was wanting to him. Born as long ago as the 26th of December, 1792, he has enjoyed a

working life of nearly eighty years, and, though within the last few years his memory for immediate events and persons was rapidly decaying, the other intellectual powers seemed as strong as ever. The series of publications which constitute the real record of his life commenced in 1813 with the preface to the *Transactions of the Analytical Society*, a small club established by Babbage, Herschel, Peacock, and several other students at Cambridge, to promote, as it was humorously expressed, the principles of pure D-ism, that is, of the Leibnitzian notation and the methods of French mathematicians. Until 1822 Mr. Babbage's writings consisted exclusively of memoirs upon mathematical subjects, which, however little read in the present day, are yet of the highest interest, not only because they served to awaken English mathematicians to a sense of their backward position, but because they display the deepest insight into the principles of symbolic methods. His memoir in the "*Cambridge Philosophical Transactions*" for 1826, "*On the Influence of Signs in Mathematical Reasoning*" may be mentioned as an admirable example of his mathematical writings. In this paper, as in many other places, Mr. Babbage has expressed his opinion concerning the wonderful powers of a suitable notation in assisting the human mind.

As early as 1812 or 1813 he entertained the notion of calculating mathematical tables by mechanical means, and in 1819 or 1820 began to reduce his ideas to practice. Between 1820 and 1822 he completed a small model, and in 1823 commenced a more perfect engine with the assistance of public money. It would be needless as well as impossible to pursue in detail the history of this undertaking, fully stated as it is in several of Mr. Babbage's volumes. Suffice it to say that, commencing with 1,500*l.*, the cost of the Difference Engine grew and grew until 17,000*l.* of public money had been expended. Mr. Babbage then most unfortunately put forward a new scheme for an Analytical Engine, which should indefinitely surpass in power the previously-designed engine. To trace out the intricacies of negotiation and misunderstanding which followed would be superfluous and painful. The result was that the Government withdrew all further assistance, the practical engineer threw up his work and took away his tools, and Mr. Babbage, relinquishing all notions of completing the Difference machine, bestowed all his energies upon the designs of the wonderful Analytical Engine. This great object of his aspirations was to be little less than the mind of a mathematician embodied in metallic wheels and levers. It was to be capable of any analytical operation, for instance solving equations and tabulating the most complicated formulae. Nothing but a careful study of the published accounts can give an adequate notion of the vast mechanical ingenuity lavished by Mr. Babbage upon this fascinating design. Although we are often without detailed explanations of the means, there can be little doubt that everything which Mr. Babbage asserted to be possible would have been theoretically possible. The engine was to possess a kind of power of prevision, and was to be so constructed that intentional disturbance of all the loose parts would give no error in the final result.

Although for many years Mr. Babbage entertained the intention of constructing this machine, and made many preparations, we can hardly suppose it capable of practical realisation. Before 1851 he appears to have despaired of its completion, but his workshops were never wholly closed. It was his pleasure to lead any friend or visitor through these rooms and explain their contents. No more strange or melancholy sight could well be seen. Around these rooms in Dorset Street were the ruins of a life time of the most severe and ingenious mental labours perhaps ever exerted by man. The drawings of the machine were alone a wonderful result of skill and industry; cabinets full of tools, pieces of mechanism, and various

contrivances for facilitating exact workmanship, were on every side, now lying useless.

Mr. Babbage's inquiries were not at all restricted to mathematical and mechanical subjects. His work on the "*Economy of Manufactures and Machinery*," first published in 1832, is in reality a fragment of a treatise on Political Economy. Its popularity at the time was great, and, besides reprints in America, translations were published in four Continental languages. The book teems with original and true suggestions, among which we find the system of Industrial Partnerships now coming into practice. It is, in fact, impossible to overpraise the work, which, so far as it goes, is incomparably excellent. Having assisted in founding the Statistical Society of London in 1834, Mr. Babbage contributed to their *Transactions* a single paper, but as usual it was a model research, containing a complete analysis of the operations of the Clearing House during 1830. It was probably the earliest paper in which complicated statistical fluctuations were carefully analysed, and it is only within the last few years that bankers have been persuaded by Sir John Lubbock to recognise the value of such statistics, and no longer to destroy them in secret. In this, as in other cases, many years passed before people generally had any notion of the value of Mr. Babbage's inquiries; and there can be little doubt that, had he devoted his lofty powers to economic studies, the science of Political Economy would have stood by this time in something very different from its present pseudo-scientific form.

Perhaps the most admirable of all his writings was the Ninth Bridgewater Treatise, an unexpected addition to that well-known series, in which Mr. Babbage showed the bearing of mathematical studies upon theology. This is one of the few scientific works in which the consistency of natural laws with breaches of continuity is clearly put forth. That Power which can assign laws can set them aside by higher laws. Apart from all particular theological inferences, there can be no question of the truth of the views stated by Babbage; but the work is hardly more remarkable for the profundity of its philosophy than for the elevated and eloquent style in which it was written, although as usual an unfinished fragment.

Of all Mr. Babbage's detached papers and volumes, it may be asserted that they will be found, when carefully studied, to be models of perfect logical thought and accurate expression. There is, probably, not a sentence ever penned by him in which lurked the least obscurity, confusion, or contradiction of thought. His language was clear, and lucid beyond comparison, and yet it was ever elegant, and rose at times into the most unaffected and true eloquence. We may entertain some fear that the style of scientific writing in the present day is becoming bald, careless, and even defective in philosophic accuracy. If so, the study of Mr. Babbage's writings would be the best antidote.

Let it be granted that in his life there was much to cause disappointment, and that the results of his labours, however great, are below his powers. Can we withhold our tribute of admiration to one who throughout his long life inflexibly devoted his exertions to the most lofty subjects? Some will cultivate science as an amusement, others as a source of pecuniary profit, or the means of gaining popularity. Mr. Babbage was one of those whose genius urged them against everything conducive to their immediate interests. He nobly upheld the character of a discoverer and inventor, despising any less reward than to carry out the highest conception which his mind brought forth. His very failures arose from no want of industry or ability, but from excess of resolution that his aims should be at the very highest. In these money-making days can we forget that he expended almost a fortune on his task? If, as people think, wealth and luxury are corrupting society, should they omit to honour one of whom it may be truly said, in the words of Merlin, that the single wish of his heart was "to give them greater minds"?

A NEW FORM OF SENSITIVE FLAME

MR. PHILIP BARRY, of Cork, has sent the following account of a new and very beautiful sensitive flame to Prof. Tyndall:—"It is in my experience the most sensitive of all sensitive flames, though from its smaller size is not so striking as your vowel flame. It possesses the advantage that the ordinary pressure in the gas mains is quite sufficient to develop it. The method of producing it consists in igniting the gas (ordinary coal gas) not at the burner but some inches above it, by interposing between the burner and the flame a piece of wire gauze.

"With a pressure of $\frac{1}{10}$ ths at the burner, I give a sketch of the arrangement I adopted, the space between burner and gauze being two inches. The gauze was about seven

inches square, resting on the ring of the retort-stand—ordinary window-blind wire-gauze 32 meshes to the lineal inch. The burner was Sugg's steatite pin-hole burner, the same as used for vowel flame.

"The flame is a slender cone about four inches high, the upper portion giving a bright yellow light, the base being a non-luminous blue flame. At the least noise this flame roars, sinking down to the surface of the gauze, becoming at the same time almost invisible. It is very active in its responses, and being rather a noisy flame, its sympathy is apparent to the ear as well as the eye.

"To the vowel sounds it does not appear to answer so discriminately as the vowel flame. It is extremely sensitive to A. very slightly to E, more so to I, entirely insensitive to O, but slightly sensitive to U.

"It dances in the most perfect manner to a small musical snuff box, and is highly sensitive to most of the sonorous vibrations which affect the vowel flame, though it possesses some points of difference."

NOTES

THE following telegram has been received from the English Government Eclipse Expedition:—"On board the *Mirapore*, Malta, Saturday, November 4. We have arrived here in safety. All the members of the Eclipse Expedition are quite well, no thanks, however, to the weather, which during the voyage has been very bad. It was so bad that there was no possibility of practising with the instruments. Last night Mr. Lockyer, at the request of all on board the *Mirapore*, gave a scientific lecture with experiments. You may form some idea of the novel character with which the lecture was invested when I state that it was blowing half a gale at the time."

SIR RODERICK MURCHISON has appointed Professor Archibald Geikie, of Edinburgh, his literary executor, and has left him a legacy of 1,000*l*. The Professor will write Sir Roderick's life, for which the deceased baronet had collected ample materials. Sir Roderick has also bequeathed to each of the professors at Jermyn Street a little remembrance of 100*l*. To the institution itself he has left the diamond snuff-box and the magnificent Siberian aventurine vase, mounted on a porphyry pedestal, presented to him by the late Emperor of Russia. He has not been unmindful of the scientific societies with which he has been so long connected. To the Geological and Geographical Societies he has bequeathed legacies of 1,000*l* each, for the purpose of furthering the cause of science by rewarding men of science by prizes or otherwise as may be deemed proper. To old associates with him in his work he has likewise left legacies as expressions of his regard. Besides that to Mr. Geikie, sums of 350*l* are appropriated for Prof. John Morris, Prof. T. Rupert Jones, Mr. Trenham Reeks, and Mr. Bates, and a sum of 100*l*. to Mr. C. W. Peach. We believe also that in the event of the failure of some of the heirs designated in the will, considerable sums are to go to various charitable and scientific institutions.

IN addition to the appointments to the governing bodies of the public schools, made by the Senate of the University of London, which we announced last week, the Council of the Royal Society has made the following:—Prof. P. M. Duncan, for Charterhouse; Prof. Tyndall, for Harrow; Prof. Henry J. Smith, for Rugby; Sir James Paget, Bart., for Shrewsbury; and the Rev. Prof. Price, for Winchester School.

PROF. P. M. DUNCAN, F.R.S., of King's College, has been appointed Lecturer on Geology to the India Civil Engineering College, Cooper's Hill.

WE learn from the *Poll Mall Gazette* that a mixed Committee has been appointed by the authorities of the War-Office, to conduct an inquiry into the safety of gun-cotton, and to make the necessary experiments. The committee will also be required to collect evidence with regard to its value as an explosive agent; and generally to pronounce as to the suitability and safety of the material for use in torpedoes, breaching stockades, mining, &c. The Committee consists of Colonel Younghusband, R.A., president; Colonel Milward, R.A., Colonel Galloway, R.E., Lieutenant-Colonel Nugent, R.E., Captain Field, R.N., Dr. Odling, F.R.S., Mr. H. Baerman, and Mr. G. Bidder, C.E. The question of the safety of the new explosive "Lithofracteur," which a German firm is anxious to be permitted to make in this country, has also been referred to the same Committee.

MR. G. M. SEABROKE, the Temple Observer at Rugby, states, in a letter to the *Times*, for the information of those who possess telescopes of moderate aperture, that Encke's comet is now within their reach. It has been examined at the Rugby Observatory with an 8½ in. aperture, and was very plainly seen. It has somewhat the shape of a fan, and there is a marked condensation on the eastern side, being the leading portion of the

comet. It would probably now be seen with a much smaller aperture than that mentioned above, and, as it is approaching us, small telescopes will probably soon show it.

THE German Astronomical Society has recently held its triennial meeting at Stuttgart, under the presidency of Prof. Otto Struve. The gathering was eminently a social one; after papers read in the morning, they adjourned for excursions in the afternoon, one day visiting the birth-place of Kepler, a small town about an hour by rail from Stuttgart. The inhabitants, who have recently erected a bronze statue to their great fellow townsman, decorated it with flowers for the occasion.

THE Scientific Societies have now mostly commenced their winter session. The greater number held their first meeting either last or during the present week. The first meeting of the Royal Society for the season is on November 16.

THE Annual General Meeting of the five Academies which constitute the Institute of France was held on the 25th of October, the anniversary of the day on which the Institute was established by the famous Directory suppressed by the first Napoleon. The third Napoleon, by an Imperial decree, changed the day of the anniversary meeting from that instituted by the Republic to his *file* day, the 15th of August. Last year the meeting was not held, and on the present occasion the original date has been resumed. The presidency of the Institute is filled each year by the president of one of the five academies in rotation, the Académie des Sciences, Académie Française, Académie des Sciences Morales et Politiques, Académie des Beaux Arts, and Académie des Inscriptions et Belles Lettres. This year it is occupied by M. Jules Simon, president of the Académie Française, to which belong M. Thiers himself and four of his colleagues in the Government, including M. Simon. The annual address for the Académie des Sciences was delivered by General Morin, and dealt chiefly with military science, especially with the inventions of the great artillery officer General Piobert.

MR. J. J. MURPHY delivered the opening address to the Belfast Natural History and Philosophical Society for the current session. It was occupied chiefly with a *résumé* of the most important fresh applications of applied science during the year.

MR. RUTHERFORD, of New York, the most eminent American amateur astronomer, and especially known for his magnificent photographs of celestial bodies, has lately presented to Mr. Brothers, the English astronomical photographer, three superb negatives of the moon—one representing her in the first quarter, one when full, and one in the third quarter; and it is proposed to publish these in a volume containing about one hundred pages of descriptive letterpress. The work will also contain a map of the moon, as we see her, and a chart, on the stereographic projection, showing the true shape and the relative dimensions of all the chief lunar features. The letterpress, map, and stereographic chart will be prepared by Mr. Proctor; the photographs by Mr. Brothers. The work will be got out on a magnificent scale, and sold at a guinea and a half to subscribers.

MESSRS. TRÜBNER announce the proposed publication of a new magazine, *The Pioneer*; a monthly journal of Sociology, Psychology, and Biology. The great aim which the *Pioneer* has in view will be "the expression of truly philosophic principles, and their application to human progress and welfare. The opinions of all will be treated with respect when expressed with the clearness and force arising from strong conviction." The subjects of "Psychic Force" and Anthropology are especially alluded to in the prospectus as coming within the range of the proposed serial.

THE Geological Expedition to the Rocky Mountain region under the charge of Dr. Hayden, to which we have already made brief allusion, according to *Harper's Weekly*, had reached Fort

Hall, Idaho, on the 18th of September. After completing the survey of the Yellow Stone Valley, the party left Fort Ellis on the 5th of September, passing down Gallatin Valley to the Three Forks, and thence by the Jefferson to its very source, exploring many of its branches, and pursuing a direction nearly parallel to that which the party had traversed in the June previous. The valleys of the Gallatin, Madison, and Jefferson forks of the Missouri, with all the little branches, were found occupied by industrious farmers and miners—a contrast quite striking to the doctor, who, twelve years ago, in exploring that same region, met with not a single white inhabitant. The Rocky Mountain Divide was crossed at the Horse Plain Creek, from which the party passed over into Medicine Lodge Creek, following this down into the Snake River Plain. An interesting fact observed was the occurrence of two species of trout in great quantities in streams such as Medicine Lodge, Camas, and other creeks all sinking into the plains after a course of from fifty to seventy-five miles. The trout appeared to be of the same two species in all, although the waters had no apparent connection. The party expected to leave Fort Hall, and to proceed to Fort Bridger by way of Soda Springs, Bear Lake, and Evanston, and there to disband the scientific corps returning to the East.

IN a very important paper on the "Estimation of Antimony," published in the *Chemical News*, Hugo Tamm calls the attention of chemists to a new phenomenon which the author describes under the name of "Hygraffinity." This phenomenon was discovered in a peculiar compound of antimony—bigallate of antimony. This compound is totally insoluble in water, and yet it possesses a powerful affinity for moisture, which it absorbs rapidly from the air after being dried at the temperature of 100° Cent. Most powders and precipitates, as it is well known, dried at that temperature, absorb moisture on exposure to the atmosphere, but this is a purely physical phenomenon due to porosity. On the contrary, in the case of gallate of antimony, chemical affinity is at work, and this precipitate, after exposure to the air for two or three hours, actually absorbs two equivalents of water. In a word, this insoluble substance has as much affinity for moisture as deliquescent salts. But one of the most curious features in connection with this extraordinary phenomenon is that on being dried at 100° Cent., bigallate of antimony loses the two equivalents of water which it had absorbed from the air, and that on being left exposed once more to the atmosphere, it reabsorbs the same amount of moisture. This interesting experiment may be repeated indefinitely.

IN the *Comptes Rendus* for August and in the *Philosophical Magazine*, M. Angström gives an analysis of the spectra which are observed in connection with hydrogen, and criticises the conclusions of M. Wüllner "that hydrogen has no less than four and oxygen no less than three distinct spectra." He explains that the spectrum lines of hydrogen (as observed by Plücker in rare hydrogen) spread out in disruptive discharges when the tension of the gas is increasing, and end by uniting so as to form a continuous spectrum. With regard to M. Wüllner's second spectrum of hydrogen, he points out that it is no other than the spectrum observed by M. Berthelot and ascribed by him to *acetylene*. Also, by a comparison of wave-lengths for sulphur and for M. Wüllner's third hydrogen-spectrum, he shows this to be in all probability the spectrum of sulphur. M. Angström also points out the close agreement between one of the oxygen spectra of M. Wüllner and the spectrum of oxide of carbon, and his tables show also a very close agreement between another of these oxygen spectra and the spectrum of chlorine, and concludes that neither oxygen nor hydrogen has more than one spectrum.

PROF. YOUNG has communicated to the *Philosophical Magazine* a catalogue of more than a hundred bright lines in the spectrum of the chromosphere, in which the observed lines are referred

to the scales of Kirchhoff's and of Angström's maps. Of the seventy new lines which are given in this list, there are two which are proved to belong to the chromosphere, and not to be due to the exceptional elevation of matter to heights where it does not properly belong. No less than twenty of these lines are due to the metal titanium, and show the presence of titanium vapour in the prominences and chromosphere.

THE cultivation of beet-root sugar in France has now risen to an industry of the first importance. It employs more than 400 manufactories, and the process of manufacture is each year brought to a higher state of perfection. There are in France three or four journals specially devoted to subjects connected with the manufacture, its cultivation, its sale, the machinery required, the chemistry of the process, &c.

THE Fourth Annual Report is published of the Trustees of the Peabody Museum of American Archaeology and Ethnology at Cambridge, U.S.A. Two important series of explorations have been carried out in the course of the past year on behalf of the Museum, by the Rev. F. O. Dunning in Eastern Tennessee, and by Dr. Berendt in Central America, resulting in valuable acquisitions to its collections. The Museum has also been enriched during the year by the gift of the "Charles Hammond Collection" from the towns of Chatham and Rochester, Cape Cod, and by a very valuable series of about 125 objects from the conservator of the Christy collection in London, consisting of original specimens and casts from Les Eyzies, La Madelaine, and Le Moustier, in the department of Dordogne, France. The Report is accompanied by a set of comparative measurements of crania from Peru, presented by Mr. Squier, of those from the mounds of Kentucky obtained by Mr. Lyon, and from the mounds of Florida.

THE Annual *Conversazione* of the Royal Society of Victoria was held on August 14, when the president, Mr. R. L. J. Ellery, delivered an address, in which he referred especially to the scientific results of the eclipse of last winter, and the preparations making in Australia for observing the eclipse of next month, to Prof. Heis's observations on the correspondence of auroral phenomena in the southern and northern hemispheres, to Dr. von Mueller's botanical researches in the colony, to the very important subject, economically, to the colony of the preservation of meat, and to Prof. Tyndall's germ theory of disease.

THE Report is published of the Annual Meeting of the Academy of Sciences of Vienna, held on the 30th of May, 1871, containing a review of the proceedings of the various departments of the Academy during the past year. The Academy has also issued its "Almanack," with list of home, foreign, and honorary members.

A SUPPLEMENT to the Sixth and Seventh Annual Report of the "Verein für Erdkunde" at Dresden, by D. Abendroth, contains a very interesting series of maps, illustrating the extent of geographical knowledge of the world possessed at different periods from A.D. 1350 to 1566.

A WORK has come out in Holland which particularly interests those who are engaged in the treatment of sewage manure. It is by M. J. A. C. Eschauzler, and gives all the results of the centuries of experience in the Netherlands. It is copiously illustrated.

WE are informed that the German translation of Tylor's "Primitive Culture" is not by Dr. Spengel, but conjointly by Herr Spengel and Herr Poske.

A NEW class for civil engineering has been formed in the Presidency College, Calcutta.

THE GEOGNOSY OF THE APPALACHIANS AND THE ORIGIN OF CRYSTALLINE ROCKS*

II.

THE characteristic examples already given of symmetrical and asymmetrical envelopment are cited from a great number of others which might have been mentioned. Very many of these are by the pseudomorphs regarded as results of partial alteration. Thus, in the case of associated crystals of andalusite and cyanite, Bischof does not hesitate to maintain the derivation of andalusite from the latter species by an elimination of quartz; more than this, as the andalusite in question occurs in a granite-like rock, he suggests that itself is a product of the alteration of orthoclase. In like manner the mica, which in some cases coats tourmaline, and in others fills hollow prisms of this mineral, is supposed to result from a subsequent alteration of crystallised tourmaline. So in the case of shells of leucite filled with feldspar, or of garnet enclosing epidote or chlorite or quartz, a similar transformation of the interior is supposed to have been mysteriously effected, while the external portion of the crystal remains intact. Again the aggregates of tinstone, quartz and orthoclase having the form of the latter, are, by Bischof and his school, looked upon as results of a partial alteration of previously formed orthoclase crystals. It needed only to extend this view to the crystals of calcite enclosing sand-grains, and regard these as the result of a partial alteration of the carbonate of lime. There is absolutely no proof that these hard crystalline substances can undergo the changes supposed, or can be absorbed and modified like the tissues of a living organism. It may, moreover, be confidently affirmed that the obvious facts of envelopment are adequate to explain all the cases of association upon which this hypothesis of pseudomorphism by alteration has been based. Why the change should extend to some parts of a crystal and not to others, why in some cases the exterior of the crystal is altered, while in others the centre alone is removed and replaced by a different material, are questions which the advocates of this fanciful hypothesis have not explained. As taught by Blum and Bischof, however, these views of the alteration of mineral species have not only been generally accepted, but have formed the basis of the generally received theory of rock-metamorphism.

Protests against the views of this school have, however, not been wanting. Scherer, in 1846, in his researches in Polymeric Isomorphism,† attempted to show that ilolite and apasolite, a hydrous species which had been looked upon as resulting from its alteration, were isomorphous species crystallising together, and, in like manner, that the association of olivine and serpentine in the same crystal, at Snarum in Norway, was a case of envelopment of two isomorphous species. In both of these instances he maintained the existence of isomorphous relations between silicates in which 3HO replaced MgO. He hence rejected the view of Gustav Rose that these serpentine crystals were results of the alteration of olivine, and supported his own by reasons drawn from the conditions in which the crystals occur. In 1853 I took up this question, and endeavoured to show that these cases of isomorphism described by Scherer entered into a more general law of isomorphism pointed out by me among homologous compounds differing in their formulas by nM_2O_2 (M=hydrogen or a metal). I insisted, moreover, on its bearing upon the received views of the alteration of minerals, and remarked, "The generally admitted notions of pseudomorphism seem to have originated in a too exclusive plutonism, and require such varied hypotheses to explain the different cases, that we are led to seek for some more simple explanation, and to find it, in many instances, in the association and crystallising together of homologous and isomorphous species."‡ Subsequently, in 1860, I combated the view of Bischof, adopted by Dana, that "regional metamorphism is pseudomorphism on a grand scale," in the following terms:—

"The ingenious speculations of Bischof and others, on the possible alteration of mineral species by the action of various saline and alkaline solutions, may pass for what they are worth, although we are satisfied that by far the greater part of the so-called cases of pseudomorphism in silicates are purely imaginary, and, when real, are but local and accidental phenomena. Bischof's notion of the pseudomorphism of silicates like feldspars and py-

* Address of Prof. T. Sterry Hunt on retiring from the office of President of the American Association for the Advancement of Science; abridged from the "American Naturalist."

† *Pogg. Annal.*, lxxvii. 319.

‡ *Ibid.*

roxenes, presupposes the existence of crystalline rocks, whose generation this neptunist never attempts to explain, but takes his starting-point from a plutonic basis.*

I then asserted that the problem to be solved in regional metamorphism is the conversion of sedimentary strata, "derived by chemical and mechanical agencies from the ocean waters and pre-existing crystalline rocks into aggregations of crystalline silicates. These metamorphic rocks, once formed, are liable to alteration only by local and superficial agencies, and are not, like the tissues of a living organism, subject to incessant transformations, the pseudomorphism of Bischof."[†]

I had not, at that time, seen the essay by Delesse on pseudomorphs already referred to, published in 1859, in which he maintained views similar to those set forth by me in 1853 and 1860, declaring that much of what had been regarded as pseudomorphism had no other basis than the observed associations of minerals, and that often "the so-called metamorphism finds its natural explanation in envelopment." These views he ably and ingeniously defended by a careful discussion of the whole range of facts belonging to the history of the subject.

My own expression of opinion on this question, in 1853, had been privately criticised, and I had been charged with a want of comprehension of the question. It was, therefore, with no small pleasure, that I not only saw my views so ably supported by Delesse, but read the language of Carl Friedrich Naumann, who in 1861 wrote to Delesse as follows, referring to his essay just noticed:—

"You have rendered a veritable service to science in restricting pseudomorphs to their true limits, and separating what had been erroneously united to them. As you have remarked, envelopments have, for the most part, nothing in common with pseudomorphs, and it is inconceivable that they have been united by so many mineralogists and geologists. It appears to me, moreover, that they commit an analogous error when they regard gneisses, amphibolites, &c., as being, all of them, the results of metamorphic epigenesis, and not original rocks. It is precisely because pseudomorphism has been so often confounded with metamorphism that this error has found acceptance. I only admit a pseudomorph where there is some crystal the form of which has been preserved. There are very many metamorphic substances which are, in no sense of the word, pseudomorphs. Had the name of crystalloid been chosen instead of pseudomorph, this confusion would certainly have never found its way into the science. I think, with you, that the envelopment of two minerals is most generally explained by a contemporaneous and original crystallisation. Secondary envelopments, however, exist, and such may be called pseudomorphs or crystalloids, if they reproduce exactly the form of the crystal enveloped, whether this last still remains, or has entirely disappeared."[‡]

It is unnecessary to remark that the view of Delesse and Naumann—viz. : that the so-called cases of pseudomorphism, on which the theory of metamorphism by alteration has been built, are, for the most part, examples of association and envelopment, and the result of a contemporaneous and original crystallisation—is identical with the view suggested by Scherer, and generalised by myself long before, when, in 1853, I sought to explain the phenomena in question by "the association and crystallising together of homologous and isomorphous species."

Later in 1862, I wrote as follows:—

"Pseudomorphism, which is the change of one mineral species into another, by the introduction or the elimination of some element or elements, presupposes metamorphism (*i.e.*, metamorphic or crystalline rocks), since only definite mineral species can be the subjects of this process. To confound metamorphism with pseudomorphism, as Bischof and others after him have done, is therefore an error. It may be further remarked, that, although certain pseudomorphic changes may take place in some mineral species, in veins and near the surface, the alteration of great masses of silicified rocks by such a process is as yet an unproved hypothesis."[§]

Thus this unproved theory of pseudomorphism, as taught by Bischof, does not, even if admitted to its fullest extent, advance us a single step towards a solution of the problem of the origin of the various silicates, which, singly or intermingled, make up beds in the crystalline schists. Granting, for the sake of argument, that serpentine results from the alteration of olivine or

labradorite, and steatite or chlorite from hornblende, the origin of these anhydrous silicates, which are the subjects of the supposed change, is still unaccounted for. The explanation of this shortsightedness is not far to seek; as already remarked, Bischof, although a professed neptunist, starts from a plutonic basis. When the epigenic origin of serpentine and its related rocks was first taught, these were regarded as eruptive and unstratified, and it was easy to imagine intruded masses of dioritic and feldspathic rocks, which had become the subjects of alteration. As, however, the progress of careful investigation in the field has shown the stratified character of these serpentines, diallage-rocks, steatites, &c., and their intercalation among limestones, argillites, quartzites, gneisses, and mica-schists, and even among feldspathic and hornblende strata, we are forced to reject, with Naumann, the notion of their epigenic derivation, and to regard them as original rocks.

This view brings us face to face with the problem of metamorphism as defined by me in 1860* (see *ante*). We must either admit that these crystalline schists were created as we find them, or suppose that they were once sands, clays, marls, &c.; in a word, sediments of chemical and mechanical origin, which by a subsequent process have been consolidated and crystallised. Whence, then, come these silicates of magnesia, lime, and iron, which are the sources of serpentine, hornblende, steatite, chlorite, &c.? This is the question which I proposed in that same year, when, after discussing the results of my examinations of the tertiary rocks near Paris containing layers of a hydrous silicate of magnesia related to talc in composition, among unaltered limestones and clays, I remarked that it is evident "such silicates may be formed in basins at the earth's surface, by reactions between magnesian solutions and dissolved silica;" and, after some further discussion, said, "further inquiries in this direction may show to what extent certain rocks composed of calcareous and magnesian silicates may be directly formed in the moist way."[†] Subsequently, in a paper on "The Origin of some Magnesian and Aluminous Rocks," printed in the "Canadian Naturalist" for June 1860,‡ I repeated these considerations, referring to the well-known fact that silicates of lime, magnesia, and iron-oxyl are deposited during the evaporation of natural waters, including those of alkaline springs and of the Ottawa River. Having described the mode of occurrence of the magnesian silicate sepiolite, in the Paris basin, and the related quincite, containing some iron-oxyl and disseminated in limestone, I suggested that while steatite has been derived from a compound like sepiolite, the source of serpentine was to be sought in another silicate richer in magnesia; and, moreover, that chlorite, unless the result of a subsequent reaction between clay and carbonate of magnesia, was directly formed by a process analogous to that which (according to Scheerer) has, in recent times, caused the deposition from waters of neolite, a hydrous aluminomagnesian silicate, approaching to chlorite in composition,§ "the type of a reaction which formerly generated beds of chlorite in the same way as those of sepiolite or talc." Delesse, subsequently, in 1861, in his essay on Rock-Metamorphism, insisted upon the sepiolites or so-called magnesian marls, as probably the source of steatite, and suggested the derivation of serpentine, chlorite, and other related minerals of the crystalline schists, from deposits approaching these marls in composition.|| He recalled, also, the occurrence of chromic oxyd, a frequent accompaniment of these magnesian minerals, in the hydrated iron ores of the same geological horizon with the magnesian marls in France. Delesse did not, however, attempt to account for the origin of these deposits of magnesian marls, in explanation of which I afterwards verified Bischof's observations on the sparing solubility of silicate of magnesia, and showed that silicate of soda, or even artificial hydrated silicate of lime, when added to waters containing magnesian chlorid or sulphate, gives rise, by double decomposition, to a very insoluble magnesian silicate.¶

To explain the generation of silicates like labradorite, scapolite, garnite, and saussurite, I suggested that double aluminous silicates allied to the zeolites might have been formed, and subsequently rendered anhydrous. The production of zeolitic minerals observed by Daubrée at Plombières and Luxeuil by the action of a silicated alkaline water on the masonry of ancient Roman baths, was appealed to by way of illustration. It had

there been shown by Daubrée that the elements of the zeolites had been derived in part from the waters, and in part from the mortar, and even the clay of the bricks, which had been attacked, and had entered into combination with the soluble matters of the water to form chabazite. I, however, at the same time pointed out another source of silicated minerals, upon which I had insisted since 1857, viz., the reaction between silicious or argillaceous matters and earthy carbonates in the presence of alkaline solutions. Numerous experiments showed that when solutions of an alkaline carbonate were heated with a mixture of silica and carbonate of magnesia, the alkaline silicate formed acted upon the latter, yielding a silicate of magnesia, and regenerating the alkaline carbonate; which, without entering into permanent combination, was the medium through which the union of the silica and the magnesia was effected. In this way I endeavoured to explain the alteration, in the vicinity of a great intrusive mass of dolerite, of a gray Silurian limestone, which contained, besides a little carbonate of magnesia and iron-oxide, a portion of very silicious matter, consisting apparently of comminuted orthoclase and quartz. In place of this, there had been developed in the limestone, near its contact with the dolerite, an amorphous greenish basic silicate, which had seemingly resulted from the union of the silica and alumina with the iron-oxide, the magnesia, and a portion of lime. By the crystallisation of the products thus generated it was conceived that minerals like hornblende, garnet, and epidote might be developed in earthy sediments, and many cases of local alteration explained. Inasmuch as the reaction described required the intervention of alkaline solutions, rocks from which these were excluded would escape change, although the other conditions might not be wanting. The natural associations of minerals, moreover, led me to suggest that alkaline solutions might favour the crystallisation of aluminous silicates, and thus convert mechanical sediments into gneisses and mica-schists. The ingenious experiments of Daubrée on the part which solutions of alkaline silicates, at elevated temperatures, may play in the formation of crystallised minerals, such as feldspar and pyroxene, were posterior to my early publications on the subject, and fully justified the importance which, early in 1857, I attributed to the intervention of alkaline silicates in the formation of crystalline silicated minerals.*

While, however, there is good reason to believe that solutions of alkaline silicates or carbonates have been efficient agents in the crystallisation and molecular re-arrangement of ancient sediments, and have also played an important part in the local alteration of sedimentary strata which is often observed in the vicinity of intrusive rocks, it is clear to me that the agency of these solutions is less universal than was once supposed by Daubrée and myself, and will not account for the formation of various silicated rocks found among crystalline schists, such as serpentine, hornblende, steatite, and chlorite. When I commenced the study of these crystalline strata, I was led, in accordance with the almost universally received opinion of geologists, to regard them as resulting from a subsequent alteration of paleozoic sediments, which, according to different authorities, were of Cambrian, Silurian, or Devonian age. Thus in the Appalachian region, as we have already seen, they have, on supposed stratigraphical evidence, been successively placed at the base, at the summit, and in the middle of the Lower Silurian or Champlain division of the New York system. A careful chemical examination among the unaltered paleozoic sediments, which in Canada were looked upon as the stratigraphical equivalents of the bands of magnesian silicates in these crystalline schists, showed me, however, no magnesian rocks except certain silicious and ferruginous dolomites. From a consideration of reactions which I had observed to take place in such admixtures in presence of heated alkaline solutions, and from the composition of the basic silicates which I had found to be formed in silicious limestones near their contact with eruptive rocks, I was led to suppose that similar actions, on a grand scale, might transform these silicious dolomites of the unaltered strata into crystalline magnesian silicates.

Further researches, however, convinced me that this view was inapplicable to the crystalline schists of the Appalachians; since, apart from the geological considerations set forth in the previous part of this paper, I found that these same crystalline strata hold beds of quartzose dolomite and magnesian carbonate, associated in such intimate relations with beds of serpentine, diallage, and steatite, as to forbid the notion that these silicates could have

been generated by any transformations or chemical re-arrangement of mixtures like the accompanying beds of quartzose magnesian carbonates. Hence it was that already, in 1860, as shown above, I announced my conclusion that serpentine, chlorite, and steatite had been derived from silicates like sepiolite, directly formed in waters at the earth's surface, and that the crystalline schists had resulted from the consolidation of previously formed sediments, partly chemical and partly mechanical in their origin. The latter being chiefly silico-aluminous, took, in part, the forms of gneiss and mica-schists, while from the more argillaceous strata, poorer in alkali, much of the aluminous silicate crystallised as andalusite, staurolite, cyanite, and garnet. These views were reiterated in 1853,† and further in 1864, in the following language, as regards the chemically-formed sediments: "steatite, serpentine, pyroxene, hornblende, and in many cases, garnet, epidote, and other silicated minerals are formed by a crytallisation and molecular re-arrangement of silicates generated by chemical processes in waters at the earth's surface."‡ Their alteration and crytallisation were compared to that of the mechanically formed feldspathic, silicious, and argillaceous sediments just mentioned.

(To be continued.)

THE RELATIONS BETWEEN ZOOLOGY AND PALEONTOLOGY*

MY distinguished predecessor, the late Prof. E. Forbes, appears to have been the first who undertook the systematic study of marine zoology with reference to the distribution of marine animals in space and in time. After making himself well acquainted with the fauna of the British seas to the depth of about 200 fathoms by dredging, and by enlisting the active co-operation of many friends, among whom we find MacAndrew, Barlee, Gwyn Jeffreys, William Thompson, and many others, entering enthusiastically into the new field of natural history inquiry; in the year 1841, Forbes joined Captain Graves, who was at that time in command of the Mediterranean Survey as naturalist. During about eighteen months he studied with the utmost care the conditions of the *Ægean* and its shores, and conducted upwards of 100 dredging operations at depths varying from 1 to 130 fathoms. In 1843 he communicated to the Cork meeting of the British Association an elaborate report on the mollusca and radiata of the *Ægean* Sea, and on their distribution as bearing on geology. Three years later, in 1846, he published in the first volume of the "Memoirs of the Geological Survey of Great Britain," a most valuable memoir upon the connection between the existing Fauna and Flora of the British Isles and the geological changes which have affected their area, especially during the epoch of the northern drift. In the year 1859 appeared the "Natural History of the European Seas," by the late Prof. Edward Forbes, edited and continued by Robert Godwin-Austen. In the first hundred pages of this little book Forbes gives a general outline of some of the more important of his views with regard to the distribution of marine forms. The remainder of the book is a continuation by his friend Mr. Godwin-Austen, for before it was finished an early death had cut short the career of the most accomplished and original naturalist of his time. I will give a brief sketch of the general result to which Forbes was led by his labours, and I shall have to point out that, although we are now inclined to look somewhat differently on certain very fundamental points, and although recent investigations with better appliances and more extended experience have invalidated many of his conclusions, to Forbes is due the credit of having been the first to treat these questions in a broad philosophical sense, and to point out that the only means of acquiring a true knowledge of the *rationale* of the distribution of our present fauna is to make ourselves acquainted with its history, to connect the present with the past. This is the direction which must be taken by future inquiry:—Forbes as a pioneer in this line of research was scarcely in a position to appreciate the full value of his work. Every year adds enormously to our stock of data, and every new fact indicates more and more clearly the brilliant results which are to be obtained by following his methods, and by emulating his enthusiasm and his indefatigable industry. Forbes believed implicitly, along with nearly all the leading naturalists of his time, in the immutability

of species. He says:—"Every true species presents in its individuals certain features, specific characters, which distinguish it from every other species: as if the Creator had set an exclusive mark or seal on each type." He likewise believed in specific centres of distribution. He held that all the individuals composing a species had descended from a single progenitor, or from two, according as the sexes might be united or distinct, and that, consequently, the idea of a species involved the idea of the relationship in all the individuals of common descent; and the converse, that there could be no possibility of community of descent except in living beings which possessed the same specific characters. He supposed that the original individual or pair was created at a particular spot where the conditions were suitable for its existence and propagation, and that the species extended and migrated from that spot on all sides, over an area of greater or less extent, until it met with some natural barrier in the shape of unsuitable conditions. No specific form could have more than a single centre of distribution. If its area appeared to be broken up, a patch not in connection with the original centre of distribution occurring in some distant locality, it was accounted for by the formation, through some geological change, after the first spread of the species, of a barrier which cut off part of its area, or by some accidental transport to a place where the conditions were sufficiently similar to those of its original habitat to enable it to become naturalised. No species once exterminated was ever re-created, so that in those few cases in which we find a species abundant at one period over an area, absent over the same area for a time, and recurring at a later period, it must be accounted for by a change in the conditions of the area which forced the emigration of the species, and a subsequent further change which permitted its return. Forbes defined and advocated what he called the law of "representation." He found that in all parts of the world, however far removed, and however completely separated by natural barriers, where the conditions of life are similar, species, and groups of species, occur, which, although not identical, resemble one another very closely; and he found that this similarity existed likewise between groups of fossil remains and between groups of fossils and groups of recent forms. Admitting the constancy of specific characters, these resemblances could not be accounted for by community of descent, and he thus arrived at the generalisation that in localities placed under similar circumstances, similar, though specifically distinct, specific forms were created. These he regarded as mutually representative species. Our acceptance of the doctrines of "specific centres" and of "representation," or at all events the form in which we may be inclined to accept them, depends greatly upon the acceptance or rejection of the fundamental dogma of the immutability of species, and on this point there has been a very great change of opinion within the last ten or twelve years—a change certainly due to the remarkable ability and candour with which the question has been discussed by Mr. Darwin and Mr. Wallace. I do not think that I am speaking too strongly when I say that there is now scarcely a single competent general naturalist who is not prepared to accept some form of the doctrine of evolution. There are no doubt very great difficulties in the minds of many of us in conceiving that, commencing from the simplest living being, the present state of things in the organic world has been produced solely by the combined action of "atavism," the tendency of offspring to resemble their parents closely, and "variation," the tendency of offspring to differ individually from their parents within very narrow limits; and many are inclined to believe that some law, as yet undiscovered, other than the "survival of the fittest" must regulate the existing marvellous system of extreme and yet harmonious modification. Still, it must be admitted that variation is a *vera causa*, probably capable, within a limited period, under favourable circumstances, of converting one species into what, according to our present ideas, we should be forced to recognise as a different species; and such being the case, it is perhaps conceivable that during the lapse of a period of time—still infinitely shorter than eternity—variation may have produced the entire result. The individuals composing a species have a definite range of variation strictly limited by the circumstances under which the group of individuals is placed. Except in man and in domesticated animals, in which it is artificially increased, this individual variation is usually so slight as to be inappreciable except to a practised eye; and any extreme variation which passes the natural limit in any direction clashes in some way with surrounding circumstances, and is dangerous to the life of the individual. The normal or graphic line, or "line of safety,"

of the species, lies midway between the extremes of variation. If at any period in the history of a species, the conditions of life of a group of individuals of the species are gradually altered; with the gradual change of circumstances the limit of variation is contracted in one direction and relaxed in another, it becomes more dangerous to diverge towards one side, and more desirable to diverge towards the other, and the position of the lines limiting variation is altered. The normal line, the line along which the specific characters are most strongly marked, is consequently slightly deflected, some characters being more strongly expressed at the expense of others. This deflection, carried on for ages in the same direction, must eventually carry the divergence of the varying race far beyond any limits within which we are in the habit of admitting identity of species. But the process must be, so to speak, infinitely slow. It is difficult to form any idea of ten, fifty, or a hundred millions of years; or of the relation which such periods bear to changes taking place in the organic world. We must remember, however, that the rocks of the Silurian system, overlaid by ten miles thickness of sediment, entombing a hundred successive faunas, each as rich and varied as that of the present day, are themselves teeming with fossils fully representing all the existing classes of animals except the very highest. If it is possible to imagine that this marvellous manifestation of eternal power and wisdom involved in living nature can have been worked out through the law of "descent with modification" alone, we shall certainly require from the physicists the very longest row of cyphers which they can afford. Now, although the admission of a doctrine of evolution must affect greatly our conception of the origin and *rationale* of so-called specific centres, it does not practically affect the question of their existence, or of the laws regulating the distribution of species from these centres by migration, by transport, by ocean currents, by elevations or depressions of the land, or by any other causes at work under existing circumstances. So far as practical naturalists are concerned, species are permanent within their narrow limits of variation, and it would introduce an element of infinite confusion and error if we were to regard them in any other light. The origin of species by "descent with modification" is as yet only a hypothesis. During the whole period of recorded human observation, not one single instance of the change of one species into another has been detected, and, singular to say, in successive geological formations, although new species are constantly appearing, and there is abundant evidence of progressive change, no single case has as yet been observed of one species passing through a series of inappreciable modifications into another.

ON THE OBJECTS AND MANAGEMENT OF PROVINCIAL MUSEUMS*

ALTHOUGH every intelligent person knows more or less what these institutions are, and what they ought to be, there is probably no subject, connected with the modern means of education in natural science, concerning which so much misconception or ignorance is manifested and tolerated as in the Management and Objects of our Provincial Museums. The majority of them throughout England present such examples of helpless misdirection and incapacity as could not be paralleled elsewhere in Europe. Some noteworthy exceptions there are. But generally the managers or guardians of local museums are precisely of this unfit class, and seem to have no more notion of their charge than as mere curiosity-shops, and even display less intelligence than is shown in such shops, where the cupidity or shrewdness of the dealer induces him at least to take due care of, and give a local habitation and a name to, his wares. But in the provincial museums even this care and title of information is pertinaciously withheld, and the visitors are left to do the best they can amid the surrounding bewilderment. This is commonly made up of a most puzzling jumble of heterogeneous miscellanies, arranged, or rather scattered, with an equally sovereign contempt for the convenience or instruction of the public, and indeed all in such admired disorder as may most plainly show how Chaos is come again and Confusion can make his masterpiece, and how every specimen added to the heap only tends to increase or perpetuate the miserable derangement. It looks as

* Abstract of an Address to a Meeting of the East Kent Natural History Society, at Canterbury, Oct. 12, 1871, by its Vice-President and Honorary Secretary, George Gulliver, F.R.S.

if the presiding local genius had set his wits to work in order to prove how much time and money might be most effectually expended with the least profit to a knowledge of the natural history, or any history, of the neighbourhood; and indeed for exemplifications of the solution of this knotty point we have too commonly only to appeal to the museum of the place. Instead of methodical illustrations of the natural history and antiquities of the district, we are likely to find a few good things overlaid by such a rabble-roust, such a multifarious and disorderly medley of outlandish and queer odds and ends, as are rather fitted for a laughing-stock than a sober exposition of science. Thus we are met at once in the hall and saloons by such incongruous lots as effigies of double women, elephants' teeth, nose-rings, brain-stones, tomahawks, stuffed alligators, moccasins, New Zealanders' heels, cockatoos, canoes, Babylonish bricks, cocoa nuts, bows, javelins, lions and tigers, calumets, match-locks, palm-branches, shields, monkey-stones, sugar-canes, Roman cement, Oliver Cromwell's watches, Panama hats, fabricated elephants, walking-stick insects, and numberless other eccentric things of this motley and confounded order. The garniture of Romeo's apothecary's shop, or the countryman's museum on the barn door, would be more instructive or intelligible and less ridiculous or perplexing.

It might be painful or appear invidious to inquire minutely by what means or under whose misconduct so many provincial museums have sunk into their present disgraceful confusion and uselessness; especially as it is little creditable to the intelligence of that community under the tolerance or approval of which this reproachful state of things exists. If the fault be attributed to the apathy or something worse among the majority of the rate-payers, it is one that the friends of popular government should hasten to correct. However this may be, it is enough for us to know that this notorious evil has increased, is increasing, and ought to be diminished; it will otherwise remain a foul blot on and a costly nuisance to the places under such unprofitable infiction. Hence every naturalist and antiquarian, every intelligent and honest member of the community, should be ready to lend his hand cordially to the good work of reform in this direction; more especially as soon as the truth is realised that the difficulty is by no means insuperable, but may be easily removed, is a consummation devoutly to be wished, and would involve no addition to the customary and regular expense. The remedies are sufficiently obvious, and to point out how they should be used, after having described the disorder and the necessity for them, is the object of the present observations. To this end we have, in the first place to consider what is desirable and practicable. To instruct ourselves and the rising generation, by means of local museums, in the elements of natural history generally, and in the local examples of it particularly, is obviously both practicable and desirable. For the first purpose, when indigenous specimens are wanting we must get exotic ones; and these should be limited to such typical examples only as are absolutely necessary for the elucidation of fundamental or comprehensive facts; for which purpose anatomical preparations, whether botanical or zoological, are chiefly, but not exclusively, to be esteemed. On the other hand, all and every species belonging to the district should be preserved and displayed so far as they admit it; partly for the knowledge they display of the science, but principally for the information they afford of the natural history of the locality. Antiquarian objects should be treated in a similar spirit. Thus would be collected at one view, or at least under one roof, much of that important knowledge which is within the means and scope of any country museum, so that every visitor to it might easily find therein both pleasure and profit in natural science in general and in the natural features of the locality in particular. The museum would then also be in a condition to fulfil one of its leading offices, as a centre for the meetings, lectures, and conversations on the natural history and antiquities of the district, and in this mode be available for contributions in furtherance of the special objects of local societies, and likely thus to add to the general stock of knowledge. And happily, this is now being regularly ventilated and popularised in such useful publications as the *Zoologist*, the *Field*, and *Land and Water*. When will the *Times* discover the fair and fertile field of instruction in the Provincial Museums, now lying waste for want of culture? NATURE, in a recent notice of certain donations to the Ludlow Museum, has shown a judicious sense of the subject.

But how are you to get the desirable specimens, and what are you to do with them? Most of those wildernesses miscalled Museums already possess a large quantity of objects only awaiting

and inviting intelligent attention. This will consist in a careful preparation, display, and description of them. After having been separately grouped under their respective kingdoms—the mineral, vegetable, and animal—they must be arranged according to the method of their natural relations, in their respective classes, orders, families, genera, and species; then accurately numbered, ticketed, and catalogued. Thus the otherwise chaotic mass of particular facts will fall into an orderly method, and be always ready to convey an accurate knowledge to visitors. Still further illustrations will be requisite, especially as regards fundamental and comprehensive phenomena, by preparations to display the essential characters at least of the classes and orders, and of the anatomy and physiology of the members thereof; and one or two careful dissections will be commonly sufficient for this purpose in each order. And now will arise the question, Who is to do all this work? Certainly neither by nor under the direction of "incorporations" of aldermen quite incapable of it can we expect any effectual labour of the kind. But with proper encouragement students of the different departments will, from a pure love of the subjects, not only be found to perform all this but probably more, and without the least expectation of any pecuniary reward. They will surely add important preparations and other objects to the collection, whenever it becomes manifest that such contributions will be duly appreciated and cared for; indeed, with regard to at least one Museum very zealous and skilful naturalists have only been prevented from giving such desirable aid by a knowledge that their work would simply be "missing," smothered, or destroyed, amid the carelessness and the maze of misplaced rubbish there undergoing a like fate, and most significantly and effectually warning them, and others like them, what they have to expect. Fortunately minerals and antiquities are commonly less perishable.

Having discussed what is desirable and practicable, we come to that which is neither one nor the other. And having somewhat irreverently adverted to the rubbish of so many Provincial Museums, a further explanation may be necessary, and the more so as this very accumulation of jumbled and useless materials is the sad *bête noire* of these collections, and so vigilantly intrusive as to force admission and predominance against all reasons of fitness or utility. Any disorderly materials when hurtful by being out of place fall into the character of rubbish, just as any plant is a weed when encroaching injuriously on the legitimate crop. In their proper place they may be very valuable; such they might be in the great general collection of the British Museum, or in a botanical garden. But nobody in his senses can suppose that it is either desirable or practicable for a provincial society to attempt an imitation of the vast and boundless metropolitan institution. This would be simply out of the question, and calculated only to provoke a smile, except peradventure among the guardians of the local museums. Indeed, with all the excellent arrangement, the army of properly paid experts, and immense space and appliances, the British Museum has become so crowded and unwieldy, especially for reference and use concerning British products, that some steps for an extrication of them from the surrounding masses of exotic things has become necessary. But the guardians of the Provincial Museum will reasonably ask, Granting that we have so much rubbish, what are we to do with it? Sell it if you can, or give it away; but by all means get rid of it, and that swiftly; to which end a bonfire might be the best thing. And having thus learned by experience the noxiousness of such rubbish, most resolutely and remorselessly refuse any quarter to it in future. At present this sort of lumber only occupies space and involves expense that might and ought to be employed for more useful and legitimate purposes; and how and why has already been mentioned. At the execution of the sentence many a wailing throes will out, some natural tears be shed, for the overfraught heart will speak. The very civil and complacent local genius will meekly plead for his idols, telling you how he loves them, and how some other equally wise and more potent individuals hold the same faith; and above all that the visitors to his temple have ever regarded all those very things with an admiration and delight amounting to veneration. He will refuse to be comforted by your assurance that what he says is no doubt very true, though Punch and Judy and Madame Tussaud may be almost as delightful if not quite as good in their way; but that your way is to show how the Provincial Museum may be made not to suppress or degrade but to develop and elevate the taste of the multitude; and that after all a good museum will sooner or later become more popular than a bad one.

THE SCOTTISH SCHOOL OF GEOLOGY*

I.

FOR the first time in the history of University Education in Scotland, we are to-day met to begin the duties of a Chair specially devoted to the cultivation of Geology and Mineralogy. Though Science is of no country nor kin, it yet bears some branches which take their hue largely from the region whence they sprang, or where they have been most closely followed. Such local colourings need not be deprecated, since they are both inevitable and useful. They serve to bring out the peculiarities of each climate, or land, or people, and it is the blending of all these colourings which finally gives the common neutral tint of science. This is in a marked degree true of Geology. Each country where any part of the science has been more particularly studied, has given its local names to the general nomenclature, and its rocks have sometimes served as types from which the rocks of other regions have been classified and described. The very scenery of the country, reacting on the minds of the early observers, has sometimes influenced their observations, and has thus left an impress on the general progress of the science. As we enter to-day upon a new phase in the history of Geology among us here, it seems most fitting that we should look back for a little at the past development of the science in this country. There was a time, still within the memory of living men, when a handful of ardent original observers here carried geological speculation and research to such a height as to found a new, and, in the end, a dominant school of Geology.

In the history of the Natural Sciences, as in that of Philosophy, there have been epochs of activity and then intervals of quiescence. One genius, perhaps, has arisen and kindled in other minds the flame that burned so brightly in his own. A time of vigorous research ensued, but as the personal influence waned, there followed a period of feebleness or torpor until the advent of some new awakening. Such oscillations of mental energy have an importance and a significance far beyond the narrow limits of the country or city in which they may have been manifested. They form part of that long and noble record of the struggle of man with the forces of nature, and deserve the thoughtful consideration of all who have joined or who contemplate joining in that struggle. I propose on the present occasion to sketch to you the story of one of these periods of vigorous originality, which had its rising and its setting at Edinburgh—the story of what may be called the Scottish School of Geology. I wish to place before you, in as clear a light as I can, the work which was accomplished by the founders of that school, that you may see how greatly it has influenced, and is even now influencing, the onward march of the science. I do this in no vainglorious spirit, nor with any wish to exalt into prominence a mere question of nationality. Science knows no geographical or political limits. Nor, though we may be proud of what has been achieved for Geology in this little kingdom, can we for a moment shut our eyes to the fact that these achievements are of the past, that the measure of the early promise at the beginning of this century has been but scantily fulfilled in Scotland, and that the state of the science among us here, instead of being in advance, is rather behind the time. And thus I dwell now on the example of our predecessors, solely in the hope that, realising to ourselves what that example really was, we may be stimulated to follow it. The same hills and valleys, crags and ravines, remain around us which gave these great men their inspiration, and still preach to us the lessons which they were the first to understand.

The period during which the distinctively Scottish School of Geology rose and flourished may be taken as included between the years 1780 and 1825—a brief half-century. Previous to that time Geology, in the true sense of the word, can hardly be said to have existed. Steno, indeed, more than a hundred years before, had shown, from the occurrence of the remains of plants and animals imbedded in the solid rocks, that the present was not the original order of things, that there had been upheavals of the sea into dry land and depressions of the land beneath the sea, by the working of forces lodged within the earth, and that the memorials of these changes were preserved for us in the rocks. Seventy years later, another writer of the Italian school, Lazzaro Moro, adopting and extending the conclusions of Steno, pointed to the evidence that the surface of the earth is everywhere worn away, and is repaired by the upheaving power of

earthquakes, but for which the mountains and all the dry land would at last be brought beneath the level of the waves.

But none of these desultory researches, interesting and important though they were as landmarks in the progress of science, bore immediate fruit in any broad and philosophic outline of the natural history of the globe. Men were still trammelled by the belief that the date and creation of the world and its inhabitants could not be placed further back than some five or six thousand years, that this limit was fixed for us in Holy Writ, and that every new fact must receive an interpretation in accordance with such limitation. They were thus often driven to distort the facts or to explain them away. If they ventured to pronounce for a natural and obvious interpretation, they laid themselves open to the charge of impiety and atheism, and might bring down the unrelenting vengeance of the Church.

Such was the state of inquiry when the Scottish Geological School came into being. The founder of that school was James Hutton—a man of a singularly original and active mind, who was born at Edinburgh in 1726, and died there in 1797. Educated for the medical profession, but possessed of a small fortune, which gave him leisure for the pursuit of his favourite studies, he eventually devoted himself to the study of Mineralogy. But it was not merely as rare or interesting objects, nor even as parts of a mineralogical system, that he dealt with minerals. They seemed to suggest to him constant questions as to the earlier conditions of our planet, and he was thus gradually led into the wider fields of Geology and Physical Geography. Quietly working in his study here, a favourite member of a brilliant circle of society, which included such men as Black, Cullen, Adam Smith, and Clerk of Eldin, and making frequent excursions to gather fresh data and test the truth of his deductions, he at length matured his immortal "Theory of the Earth," and published it in 1785. Associated with Hutton, rather as a friend and enthusiastic admirer than as an independent observer, was John Playfair, Professor of Natural Philosophy in this University, by whose graceful exposition the doctrines of Hutton were most widely made known to the world. His classic "Illustrations of the Huttonian Theory" is one of the most delightful books of science in our language—clear, elegant, and vivacious—a model of scientific description and argument, which I would most earnestly recommend to your notice. Sir James Hall, another of this little illustrious band, had one of the most inventive minds which have ever taken up the pursuit of science in this country. His merits have never yet been adequately realised by his countrymen, though they are better appreciated in Germany and in France. He was in fact the founder of Experimental Geology, since it was he who first brought geological speculation to the test of actual physical experiment. This he accomplished in a series of ingenious researches, whereby he corroborated some of the disputed parts of the doctrines of his master, Hutton. These were the three chief leaders of the Scottish school; but to their number, as worthy but less celebrated associates, we must not omit to add the names of Mackenzie, Webb Seymour, and Allan.

It would lead me far beyond the allotted hour to attempt any adequate summary of the work achieved by each of these early pioneers of the science. It will be enough for my present purpose if I try to sketch to you what were the leading characteristics of this Scottish School, and what claim it has to be remembered, not by us only, but by all to whom Geology is the subject either of serious study or of pleasant recreation.

Born in a "land of mountain and flood," the geology of the Scottish School naturally dealt in the main with the inorganic part of the science, with the elemental forces which have burst through and cracked and worn down the crust of the earth. It asked the mountains of its birthplace by what chain of events they had been upheaved, how their rocks, so gnarled and broken, had come into being, how valleys and glens had been impressed upon the surface of the land, and how the various strata through which these wind had been step by step built up. It encountered no rocks, like those which had arrested the notice of the early Italian geologists, charged with fossil shells, and corals, and bones of fish, such as still lived in the adjoining seas, and which at once suggested the former presence of the sea over the land. Neither did it meet, with deposits showing abundant traces of ancient lakes, and rivers, and land-surfaces, each marked by the presence of animal and plant remains, like those which set Steno and Moro thinking. The rocks of Scotland are as a whole unfossiliferous. It was, therefore, only with the records of physical events, unaided by the testimony of organic remains, that the Scottish geologists had to deal. Their task was to unravel the

* A Lecture delivered at the opening of the class of Geology and Mineralogy in the University of Edinburgh, by Archibald Geikie, F.R.S., Nov. 6, 1871.

complicated processes by which the rocky crust of the earth has been built up, and by which the present varied contour of the earth's surface has been produced,—to ascertain, in short, from a study of the existing economy of the world, what has been the history of our planet in earlier ages.

Hitherto, while men had been accustomed to believe that the earth was but some 6,000 years old, they sought in the rocks beneath and around them evidence only of the six days' creation or of the flood of Noah. Each new cosmological system was based upon that belief, and tried in various ways to reconcile the Biblical narrative with fanciful interpretations of the facts of Nature. It was reserved for Hutton to declare, for the first time, that the rocks around us can never reveal to us any trace of the beginning of things. He too first clearly and persistently proclaimed the great fundamental truth of Geology, that in seeking to interpret the past history of the earth as chronicled in the rocks, we must use the present economy of nature as our guide. In our investigations, "no powers," he says, "are to be employed that are not natural to the globe, no action to be admitted of except those of which we know the principle. Nor are we to proceed in feigning causes when those appear insufficient which occur in our experience." This was the guiding principle of the Scottish School, and through their influence it has become the guiding principle of modern Geology.

There were two directions in which Hutton laboured, and in each of which he and his followers constantly travelled by the light of the present order of nature—viz., the investigation of (1) changes which have transpired beneath the surface and within the crust of the earth, and (2) changes which have been effected on the surface itself.

1. That the interior of the earth was hot, and that it was the seat of powerful forces, by which the solid rocks could be rent open and wide regions of land be convulsed, were familiar facts, attested by every volcano and earthquake. These phenomena had been for the most part regarded as abnormal parts of the system of nature; by many writers, indeed, as well as by the general mass of mankind, they were looked upon as Divine judgments, specially sent for the punishment and reformation of the human species. To Hutton, pondering over the great organic system of the world, a deeper meaning was necessary. He felt, as Steno and Moro had done, that the earthquake and volcano were but parts of the general mechanism of our planet. But he saw also that they were not the only exhibitions of the potency of subterranean agencies, that in fact they were only partial and perhaps even secondary manifestations of the influence of the great internal heat of the globe, and that the full import of that influence could not be understood unless careful study was also given to the structure of the rocky crust of the earth. Accordingly, he set himself for years patiently to gather and meditate over data which would throw light upon that structure and its history. The mountains and glens, river-valleys and sea-coasts of his native country, were diligently traversed by him, every journey adding something to his store of materials, and enabling him to arrive continually at wider views of the general economy of nature. At one time we find him in a Highland glen searching for proofs of a hypothesis which he was convinced must be true, and, at their eventual discovery, breaking forth into such gleeful excitement that his attendant gillies concluded he must certainly have hit upon a mine of gold. At another time we read of him boating with his friends Playfair and Hall along the wild cliffs of Berwickshire, again in search of confirmation to his views, and finding, to use the words of Playfair, "palpable evidence of one of the most extraordinary and important facts in the natural history of the earth."

As a result of his wanderings and reflection, he concluded that the great mass of the rocks which form the visible part of the crust of the earth was formed under the sea, as sand, gravel, and mud are laid there now; and that these ancient sediments were consolidated by subterranean heat, and, by paroxysms of the same force, were fractured, contorted, and upheaved into dry land. He found that portions of the rock had even been in a fused state; that granite had erupted through sedimentary rocks; and that the dark trap-rocks or "whinstones" of Scotland were likewise of igneous origin.

When the sedimentary rocks were studied in the broad way which was followed by Hutton and his associates, many proofs appeared of ancient convulsions and re-formations of the earth's surface. It was found that among the hills the strata were often on end, while on the plains they were gently inclined; and the

inference was deduced by Hutton that the former series must have been broken up by subterranean commotions before the accumulation of the latter, which was derived from its *débris*. He conjectured that the later rocks would be found actually resting upon the edges of the older. His search for, and discovery of, this relation at the Siccar Point, on the Berwickshire coast, are well described by his biographer Playfair, who accompanied him, and who, dwelling on the impression which the scene had left upon him, adds: "The mind seemed to grow giddy by looking so far into the abyss of time; and while we listened with earnestness and admiration to the philosopher who was now unfolding to us the order and series of these wonderful events, we became sensible how much farther reason may sometimes go than imagination can venture to follow." Sir James Hall afterwards, by a series of characteristically ingenious experiments, showed how the rocks of that coast-line may have been contorted by movements in the crust of the earth under great superincumbent pressure.

Hutton was the first to establish the former molten condition of granite, and of many other crystalline rocks. He maintained that the combined influence of subterranean heat and pressure upon sedimentary rocks could consolidate and mineralise them, and even convert them into crystalline masses. He was thus the founder of the modern doctrines of metamorphism regarding the gradual transformation of marine sediments into the gneiss and rugged gneiss and schist of which mountains are built up. Let me quote the eulogium passed upon this part of his work in an essay by M. Daubrée, which eleven years ago was crowned with a prize by the Academy of Sciences at Paris—"By an idea entirely new, the illustrious Scottish philosopher showed the successive co-operation of water and the internal heat of the globe in the formation of the same rocks. It is the mark of genius to unite in one common origin phenomena very different in their nature." "Hutton explains the history of the globe with as much simplicity as grandeur. Like most men of genius, indeed, who have opened up new paths, he exaggerated the extent to which his conceptions could be applied. But it is impossible not to view with admiration the profound penetration and the strictness of induction of so clear-sighted a man, at a time when exact observations had been so few, he being the first to recognise the simultaneous effect of water and heat in the formation of rocks, in imagining a system which embraces the whole physical system of the globe. He established principles which, in so far as they are fundamental, are now universally admitted."

(To be continued)

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie, clix., for July, opens with a concluding communication "On the constitution of the twice substituted benzenes," by E. Ador and V. Meyer. The authors converted sulphanilic acid into bromobenzene-sulphonic acid, and fused the potassium salt of this acid with potassic hydrate. The dihydroxybenzene produced was found to be resorcin; Meyer and others have proved that resorcin belongs to the 1:4 series, and therefore sulphanilic acid must also be regarded as containing the SO_3H and NH_2 in the places 1 and 4 respectively. Sulphanilic acid treated with nitrous acid yields a diazo-derivative $\text{C}_6\text{H}_4\text{N}_2\text{SO}_3$, this on boiling with water is converted into phenol-sulphonic acid, which was found to be identical with Kekulé's parafenolsulphonic acid. At the end of the communication, a valuable table of the twice substituted benzenes, showing the place of attachment of the second substituted group is given; it however differs in some respects from the arrangement of other chemists. Ernst and Zwenger have prepared ethyl and amyl gallates by passing hydrochloric acid through a boiling solution of gallic acid in the anhydrous alcohols; at present they have not succeeded in preparing the methyl gallate.—A very exhaustive paper follows "On some substances crystallised from microcosmic salt and from borax," by A. Knop, in which the crystallisation of phosphotannic, phosphozirconic, and phosphoniobic acids from microcosmic salt, and of stannic acid, zirconic acid, niobiac, and niobic acid from borax are thoroughly discussed.—Lieben and Kossel have prepared "normal valeric acid" by the action of boiling alcoholic potash on butyl cyanide, they find that the valeric acid thus obtained does not agree in properties with either of the acids already known. They have also prepared normal amyl alcohol from the above acid, by heating the calcic valerate with calcic formiate, the valeric aldehyde being converted into amyl alcohol by the action of sodium amalgam. The alcohol

* Hutton's "Theory of the Earth," i. p. 160; ii. p. 549.

obtained boiled at 137°, which is somewhat higher than that of the ordinary alcohol. The normal amyl chloride, bromide, iodide, and acetate have been prepared, all of which possess boiling points higher than those of the compounds obtained from the fermentation alcohol. Normal caproic acid was prepared from amyl cyanide in the same manner as the valeric acid previously described.—A translation of Rossi's paper "On the synthesis of normal propyl alcohol from ethyl alcohol," and also of T. Smith's paper "On the estimation of the alkalies in silicates" follow.—Tollens continues with the seventh contribution on the allyl group, the subject of which is the conversion of allyl alcohol into propyl alcohol; this is accomplished by treating allyl alcohol with solid potash, the temperature being gradually raised to 155°, hydrogen being evolved in the reaction; it was found extremely difficult to purify the propyl alcohol; to obtain conclusive evidence it was converted into propionic acid; some six or eight other bodies are formed in this reaction, such as formic acid, propionic acid, and other higher compounds.—Rinne and Tollens have succeeded in preparing allyl cyanide from the bromide by the repeated action of potassic cyanide, and have converted it into crotonic acid by the action of alcoholic potash; the crotonic acid obtained fused at 72°, and possessed all the properties of crotonic acid as made from allyl cyanide prepared from mustard-oil. By the oxidation of allyl alcohol by chromic acid the authors have obtained formic acid, and small quantities of acrylic acid, no acetic acid being produced.—Fittig contributes a paper "On the alleged dibasic nature of gluconic and lactic acids," being a reply to Hlasiwetz's paper on this subject, Fittig himself considering them monobasic.—The continuation of a paper "On the action of Sulphuric Acid on Platinic Chloride," by K. Birnbaum, follows, several new and complicated salts of this series have been obtained; the reactions seem to proceed in two stages, first a reduction to platinum chloride takes place, and then the substitution of Cl by HSO₃; thus by the action of hydric ammoniac sulphite on ammoniac chloroplatinate a body of the composition

$$\text{Pt} \begin{matrix} \text{Cl} & \text{NH}_4 \\ \text{HSO}_3 & \text{H} \end{matrix} \text{SO}_3 + 4 \text{H}_2\text{O} \text{ is obtained.}—\text{This number concludes with two short papers by J. Myers. The first is "On the temperature of decomposition of sulphuretted hydrogen," this is placed between 350° and 400°, probably nearer the lower temperature; the second paper is "On sulphuretted hydrogen containing arsenic." Sulphuretted hydrogen, as usually prepared from impure sulphuric acid and ferrous sulphide, contains a gaseous arsenic compound, probably arsenetted hydrogen; the two gases do not react on each other at ordinary temperatures, but when they are heated to the boiling point of mercury, a deposit of arsenious sulphide takes place. The arsenetted hydrogen is probably produced by the action of nascent hydrogen on the arsenic compound existing in the sulphuric acid.$$

SOCIETIES AND ACADEMIES

LONDON

Royal Microscopical Society, November 1.—W. Kitchen Parker, F.R.S., president, in the chair. Dr. Braithwaite, F.L.S., contributed further remarks on the structure of the Sphenagene, or bog-mosses. Confining himself principally to the characters for grouping the numerous species into sub-genera, he advocated the system adopted by Dr. Lindberg of Stockholm, based upon those yielded by the form of the leaves investing certain portions of the stem and divergent branches.—Mr. W. Saville Kent, British Museum, read a paper on Prof. James Clark's Flagellate Infusoria with description of new species. In his communication, Mr. Kent announced the discovery among others of Prof. Clark's minute "collared" types (*Codogira*, *Bicocerca*, &c.), first made known to the scientific world through the Memoirs of the Boston Society of Natural History for 1866, but not since corroborated by any European naturalist. Of the eleven species noticed by Mr. Kent, five were identified by him with American forms; the remaining six, while referable to corresponding genera, offering well-marked specific distinctions. The whole series are of exceedingly minute size, requiring a magnifying power of 800 diameters and upwards for the recognition of their structural peculiarities, the chief interest attached to them being their striking resemblance to the ultimate cell particles lining the incurrent cavities of sponges, as clearly shown by Prof. Clark in the calcareous, and since demonstrated

by Mr. Carter in the siliceous groups. Mr. Kent expressed his dissent from Prof. Clark's views in regard to the nutritive functions of *Monas* and other Flagellata, in the course of his investigations, he having observed the former to engulf food at any portion of its periphery, after the manner of *Amaba*, while in the collar-bearing species, it was intercepted at any portion within the area circumscribed by the base of that organ, there being in no case a distinct mouth as assumed by Prof. Clark. In the discussion that ensued, Mr. Kent assented to the President's suggestion, that the Flagellata, in the possession of one or more lash-like appendages, represented a higher type of organisation than the Foraminifera, and other Rhizopodous Protozoa; and expressed his opinion that the Spongiadae, as a class, combined the structural characters of the ordinary Rhizopoda and lower Infusoria, having superadded to this a skeletal and aggregated type of organisation essentially their own. Mr. C. Stewart affirming to having observed an appearance of three flagellate appendages to certain cells of *Leucosolenia botryoides* under a magnifying power of about 300 diameters, Mr. Kent accepted his statement as further corroboration of the existence of a membranous collar, which, under an insufficient degree of magnification, presents the aspect attested to by Mr. Stewart. The entire series of Infusorial forms recorded in Mr. Kent's communication were obtained by him from a pond on the estate of Mr. Thos. Randle Bennett, Wentworth House, Stoke Newington.

Entomological Society, November 6.—Prof. J. O. Westwood, F.R.S., vice-president, in the chair. Mr. Davis exhibited a collection of larvae of Lepidopterous and other insects, beautifully preserved by inflation. Mr. Bond exhibited examples of *Zygana esculans*, a new British moth, captured by Dr. Buchanan White in Braemar, and *Catocala Fraxini*, recently captured in the Regent's Park; also a singular variety of *Chorocampa elenor*, in which the central portion of each fore-wing was hyaline.—The Rev. A. Matthews sent for exhibition specimens of *Throsicus carinifrons* and *Cryphalus tibie*, new, or recently discovered, British Coleoptera.—Mr. M'Lachlan exhibited *Bittacus apterus* from California, recently described by him in the *Entomologists' Monthly Magazine*.—Mr. Howard Vaughan exhibited the dark form of *Triphena orbana*, from Scotland, known as *T. curvis*, and Mr. Lewis made some remarks on the synonymy of this form. Mr. Vaughan also exhibited a nearly black variety of *Arge Galathea*, captured in Kent by Mr. Tarn.—Mr. Miller exhibited an enormous oak-gall from America; also impregnated and unimpregnated eggs of *Libellula flavola*.—Prof. Westwood exhibited numerous examples of *Formica herculeana*, a gigantic ant not hitherto known as British, found in the proventriculus of an example of *Picus martius*, said to have been shot near Oxford; from the perfect condition of the ants and of the bird which had devoured them, he fully believed in the genuineness of the bird as a British example, an opinion which was not shared by some of the members present. Prof. Westwood also exhibited two male examples of *Papilio Crino* from Ceylon, in one of which some of the veins of the wings were coated with brown hairs, a usual character with the males of some species of *Papilio*, but which had not hitherto been observed in that of *Crino*.—Mr. F. Smith exhibited a *Noctua*, apparently belonging to the genus *Aploca*, which had been taken alive by Mr. Gwyn Jeffreys at sea, 220 miles from Nova Scotia.—Baron Chandois communicated notes commenting upon Mr. Wollaston's remarks respecting *Eurygnathus parvulus*, a Madeira beetle described by him, and maintaining its distinctness from *E. latreillei*.—Mr. Briggs read a paper "On *Zygana Trifolii* and allied forms," detailing the result of his observations during many years, and arriving at the conclusion that two distinct forms or species had hitherto been confounded in Britain under the name of *Trifolii*.

Linnean Society, November 2.—Mr. G. Bentham, president, in the chair. Sir John Lubbock, Bart., read a paper "On the Origin of Insects," an abstract of which will be found in another column. An interesting discussion followed, in which Mr. George Busk, Mr. A. R. Wallace, Mr. M'Lachlan, Mr. Stainton, and Mr. B. Lowne, took part.—Captain Chimmio, "Notes on the Natural History of the Flying Fish." The author considers that he has established that during flight there is an extra consumption of oxygen by the fish, as shown by an increase of temperature. He finds that life is maintained for a period of from seven to nine minutes out of the water, and states that the fish possesses the power of changing the direction of its course during flight, using its tail as a rudder.

CHESTER

Society of Natural Science, October 25.—President, Rev. Canon Kingsley; treasurer, Mr. Kinsman; hon. secretary, Mr. Manning. The society is divided into three sections: (1) botany, (2) geology, (3) zoology; and numbers nearly 200 members. Mr. Alfred O. Walker read a paper on "Objects and Organisation of Local Natural History Societies."

GLASGOW

Geological Society, October 19.—Mr. Edward A. Wünsch, vice-president, in the chair. The Annual Report and abstract of the accounts for past year showed the society to be in a flourishing condition. — Mr. James Thomson, F.G.S., read a paper "On the Plagiostomous Fishes of the Coal Measures," particularly *Orthacanthus Dechenii* Goldfuss. He observed that Prof. Agassiz, in his "Poissons Fossiles" published in 1837, described the genus *Diplodus* (sp. *gibbosus* and *minutus*) from specimens, chiefly of dissociated teeth, found in the English coal-fields. Subsequently, a well-preserved fish was discovered in Bohemia, and described in 1847 by Goldfuss, who named it *Orthacanthus Dechenii*. In 1848, Prof. Beyrich, of Berlin, described the same fish, and named it *Xenacanthus Dechenii*, founding on the fact that the spine had a greater similarity to *Pleuracanthus* than to *Orthacanthus*. At the meeting of the British Association in Glasgow in 1855, Sir Philip Egerton, from discoveries that had been made in the interval, pointed out that the spines of *Pleuracanthus* and the teeth of *Diplodus* belonged in fact to the same fish. The specimens from which Sir Philip proved this to the Association were obtained from Carlisle and Edinburgh. In 1867 Prof. Kner went carefully over the remains of such fishes in the museums of Dresden, Berlin, Breslau, and Vienna. Although none of the specimens found in these museums were complete, yet in some of them he found the teeth of *Diplodus minutus* of Agassiz in position, and from the external aspect of the fossils he accepted Goldfuss's generic name, *Orthacanthus Dechenii*. The specimen which Mr. Thomson now exhibited had been for many years in his collection, and had been provisionally named *Pleuracanthus minutus*. After a careful examination, however, of the microscopic structure both of the teeth and the sh. green, he could find no relation between the structure of *Pleuracanthus* and that now exhibited. In the meantime he accepted Prof. Kner's identification, but thought it possible that the discovery of better-preserved specimens would show that the difference of structural character might be due to difference of sex, as he had found to be the case in the recent rays' jaws of *Raja clavata*, both male and female, with the teeth in position, exhibited in support of this view.

PARIS

Academy of Sciences, October 30 — M. P. A. Favre read a continuation of his researches upon the thermal phenomena of electrolysis, accompanying an account of his investigations upon alkaline bases and sulphates; M. Wurtz presented the continuation of a paper, by M. G. Salet, on the spectra of phosphorus and of the compounds of silicon; and M. Le Verrier communicated a note by M. Diamilla-Müller, on a series of simultaneous magnetic observations which it is proposed to make in various parts of the surface of the globe, on the 15th of October, 1872. This note is accompanied by a table of the absolute magnetic declinations calculated for the above date, at a great number of places in all parts of the eastern hemisphere. — MM. Dumas and Chevreul and General Morin discussed the right of Daguerre to be regarded as the inventor of photography, and asserted the prior claims of Nicéphore de Saint-Victor. — M. Favre read the conclusion of his memoir on the history and present state of the theory of comets. — M. Delaunay presented a note by M. G. Leveau, giving the elements of the planet Hera (103). — A note was read by M. Barbe, on the uses of dynamite. — M. E. M. Raoult read a note on the transformation of dissolved cane-sugar into glucose, under the influence of light. The exposure lasted from May 12 to October 20. — M. Berthelot communicated the third part of his investigations of the ammoniacal salts, in which he discussed the reciprocal actions of the salts of ammonia and of the other alkalis. — A note was read by MM. A. Scheurer-Kestner and C. Meunier, on the composition and heat of combustion of two Welsh coals (from Bwlff and Fowel). — M. Daubrée communicated a paper on the deposit in which phosphate of lime has lately been discovered in the departments of Tarn-et-Garonne and the Lot. — M. A. Damour presented a note on an idocrase, from Arendal, in Norway, con-

taining an analysis of the mineral, and also an analysis of a garnet from Mexico. — M. E. Blanchard communicated a note by M. S. Jourdain, on the reproduction of *Helix aspersa*, in which the author described the arrangement of the reproductive organs and the mode in which their products are brought together.

NEW WORKS ON MECHANICS

Lehrbuch der Mechanik in elementarer Darstellung mit Übungen und Anwendungen auf Maschinen und Bau-Constructionen. Von Ad Wernicke. Vol. I. (Braunschweig, 1871. London: Williams and Norgate.)

Lehrbuch der physikalischen Mechanik. Von Dr. Heinrich Buff. Vol. I. (Braunschweig, 1871. London: Williams and Norgate.)

An Elementary Course of Theoretical and Applied Mechanics. By Richard Wormell. Second Edition. (London, 1871. Groombridge and Sons.)

WERNICKE'S work is intended for pupils in the Prussian industrial schools (*Gewerbeschulen*). The first volume treats of Statics and Dynamics, leaving Hydro-mechanics for the second. According to the preface, students reading this work should be acquainted with elementary mathematics, including co-ordinate geometry, while a knowledge of the differential calculus is not required. From an English point of view, it is not desirable to draw the line between co-ordinate geometry and the calculus. Even in our universities, not twenty per cent. of the students are acquainted with co-ordinate geometry. It is to be regretted that the proportion is so small; that it is so, is due to the present preposterous system of classical education, that relic of the middle ages which is the bane of our schoolboy days. Almost all English students, however, who learn co-ordinate geometry, generally study both the differential and integral calculus before commencing mechanics. Now intelligent pupils like a text-book of mechanics in which they find scope for exercising all their mathematical knowledge; hence it would appear that for English purposes the line is drawn either too high or too low.

As to the manner in which Wernicke has executed his task, it would be hard to speak too favourably; and notwithstanding the point we have raised, we should hail an English translation as a valuable addition to our standard works on mechanics. One of the best features in the book is that it presents theoretical and practical mechanics not as two distinct subjects, but in that degree of combination which naturally belongs to them.

The first volume of Wernicke's work consists of 400 octavo pages, and is divided into three parts. Part I. discusses the Kinematics of a mathematical point, the inquiry being principally confined to space of two dimensions. The symbol j is here and throughout the work used to denote an acceleration: for example, jx is the acceleration parallel to the axis of x . This notation (unfamiliar to English readers) has obvious advantages when the more appropriate language of the differential calculus cannot be employed. About fifty examples, many of a practical character, are appended to Part I. Among them is found (Ex. 31) a problem virtually requiring the integration of a^x . The solution given is necessarily roundabout and cumbersome, owing to the restraint which the author has imposed upon his use of mathematics. It may, indeed, be questioned whether a student who is not acquainted with the integral calculus could really

profit by a solution which is merely the integral calculus ground down and spoiled.

Part II. is upon the Mechanics of a material particle. We notice here small points in the diagrams which must be useful to the learner. Thus, in a figure where the length of a line is denoted by a symbol, the extremities of a bracket indicate the extremities of the line. Those who use the black-board in teaching will appreciate the advantage of this detail. Take, for example, Fig. 54, which refers to motion in an ellipse about a force in the focus. In this part and the examples appended, the usual proportions relating to the statics and dynamics of forces applied at a single point will be found.

The third part, which treats of the mechanics of a rigid body, occupies four-fifths of the volume. Chap. I. discusses the Composition and Equilibrium of Forces in space; some of the examples require a good deal of honest numerical work, others are well-known questions not involving friction. Chap. II. is on the Centre of Gravity; in this we do not notice much that is unusual, except the excellence of the illustrations. The examples contain problems on the centre of gravity of various useful areas and volumes, the theory of the arch, and many other subjects.

In Chap. III. we have a treatise upon Friction. We miss here an actual description and discussion of a series of experiments from which the laws of friction are established. This omission is to be regretted, because the laws are only approximate, and it is important for the pupil to have materials presented to him from which he can form his own estimate of their correctness. Intelligent pupils would have been pleased to find how true the laws are on the whole, and interested in noting the discrepancies. No good opportunity for introducing and discussing the results of experiments should have been lost in a work of this kind. With this exception, the force of friction has been treated in a manner worthy of its importance; we find its effect upon the various mechanical powers, upon toothed wheels and brakes, and in many other cases, treated in an excellent manner. Chap. IV., on the Motion of a rigid body, very properly commences with the exquisite kinematical theorems of Poincot. D'Alembert's principle follows, and also a table of moments of inertia, which will be found a useful aid in recollecting these troublesome quantities.

Chap. V., on Elasticity and Rigidity, is certainly the best chapter in the book. Problems connected with the deflection of a beam are among the most interesting questions of mechanics. We have here an exceedingly careful discussion of this subject, not too much encumbered with formulae. A large number of examples thoroughly worked illustrate this chapter. Every teacher of applied mechanics will find these examples invaluable; they are far better than those on the same subject in any other book with which we are acquainted.

Finally, in estimating the merits of this work, we must recollect that it is a manual for class instruction; it is not, nor does it profess to be, a comprehensive and original treatise, like the great work of Weisbach.

Buff's work, of which the first volume is before us, is of somewhat different character to that of Wernicke. It bears the same marks of painstaking thoroughness which characterise the better class of German works on science.

The illustrations are also unusually good in both books, but while Wernicke's is professedly a mathematical treatise, the work of Buff leans more to the physical aspects of mechanics. There is, however, considerable reference to mathematics in Buff, in fact, he makes free use of the calculus when necessary.

The book consists of thirteen sections:—Section I. is on Rest and Motion; Section II. on Movement in Space and Time: this contains, in addition to the usual theorems on the motion of a point, a useful article on harmonic motion. Section III. introduces the Composition of Movements; in this will be found a discussion of experiments upon the trajectory of the bullet from the needle-gun. Section V. commences the subject of Mechanical Work; we are glad to see in this book the principle of work receives that prominence which it unquestionably deserves. Section VII., on Friction, discusses, among other subjects, Pambour's experiments upon the friction of railway carriages. Section IX., upon the Efficiency of Machines, is admirable, the theory being properly proportioned to the experiments. We find here a full discussion of the subject, without that deluge of formulæ which is so often repulsive to those in search of distinct physical conceptions. Section X. contains what is familiar to us by the term Mechanism; Section XII. is the most complete account of Centrifugal Force which we have met with in any work; we have here a physical explanation of the permanent axes, of precession and nutation, of the mode of finding the masses of the heavenly bodies, and of various other matters. Section XIII., upon the Motion of the Pendulum, is a collection of interesting subjects, among them Foucault's pendulum, and a far better account of Cavendish's experiments than is to be found in any English book on mechanics. We are also a little surprised to find the weighing scales treated in this section. The arrangement is novel, and though doubtless much might be said in favour of it, yet we think, on the whole, it is not convenient.

We cordially recommend Buff's treatise to the notice of teachers of natural philosophy.

Mr. Wormell's book, which appears to have been specially intended for the London University examination for B.A. and B.Sc., contains practical and experimental illustrations, in addition to the usual matter. We should gladly welcome a thoroughly good work on the general plan which has been adopted by Mr. Wormell, but the book before us ought to receive careful revision before it is placed in the hands of students. We shall indicate some of the points that we have noticed which require correction. We do so in the belief that a future edition of the work might be made really valuable, and supply a much felt want. Some of the errors are common to this work and other text-books. We can, therefore, only accuse Mr. Wormell of reproducing them, but we cannot allow this excuse on every occasion.

On page 14, we find as follows:—"Any two forces F' , F'' applied at a point M may be transferred parallel to themselves to any other point M' in the line of direction of the resultant."

This proposition, if true, would assert that the attractions of the earth and sun upon the moon might be transferred to any heavenly body in space which happened to be in the line of direction of the resultant of the forces. The geometrical proof of the composition of parallel forces (p.

33) is meaningless, until the proposition referred to has been properly stated. This blunder is extremely common, it arises from enunciating as a property of forces what is really the definition of a rigid body.

On page 112 we find the following passage:—

"1. When the materials composing the surfaces in contact remain the same, the friction varies as the pressure. Suppose, for example, that a block of wood, having a hole bored in it, rests on a plane inclined at the angle of repose, if lead be poured in the hole, the screw may be turned so as to incline the plane at a greater angle without causing the body to slide. By increasing the pressure we increase the friction."

This is very bad; the statement we have italicised in the second paragraph is entirely erroneous. So serious an error would be quite inexcusable even in one of those for whose use the book has been written.

We should have liked to have seen more experiments upon the mechanical powers cited. A student who reads (p. 94) that in the three sheave pulley-block the power is one-sixth of the load, will naturally be surprised when he finds by trial that the power must be one-fourth of the load; nor can we find a single word in the book which would enlighten his difficulty. We should also have expected that the author would have replaced the antiquated and useless pulley systems which only exist in manuals, by some compact and useful machines like the differential pulley.

Such are some of the points which we consider to require careful revision before Mr. Wormell's book can be pronounced suitable for the use of students.

OUR BOOK SHELF

Contributions to Botany, Iconographic and Descriptive. By John Miers, F.R.S., F.L.S. Vol. 3, containing a complete Monograph of the Menispermaceæ. Sixty-six litho plates. (London: Williams and Norgate, 1864—1871.)

MR. MIERS'S long-promised Monograph of the Menispermaceæ forms the third volume of his valuable "Contributions to Botany." The intimate acquaintance of this veteran botanist with South American plants, and his long study of this particular family, extending over more than twenty years, render his observations peculiarly valuable to all systematic botanists. Although in some important particulars Mr. Miers combats the views of such high authorities as the authors of the "Flora Indica," and those of the "Genera Plantarum," he adduces reasons for his dissent, which will, at least, need careful consideration from all who hereafter write on these plants. Mr. Miers retains, with some modifications, his views of the structure of the different organs in this order published in the Annals of Natural History in 1851, and classifies the genera which constitute it into seven tribes, on characters dependent mainly on the structure of the fruit, and on the position of the cotyledons relatively to the radicle, whether incumbent or accumbent. The establishment of sixty-four distinct genera in the order, instead of the thirty-one admitted by Bentham and Hooker, may be open to criticism, but several of them contain only single species now for the first time described, which appear to be altogether aberrant types of the order. Good plates are always valuable; and we have here sixty-six, drawn on stone by the author himself, containing careful dissections to illustrate the salient characters of the genera and more important species. This concluding volume of Mr.

Miers's "Contributions to Botany" is no less valuable than any of its predecessors as a record of laborious and conscientious devotion to science.

A. W. B.

An Elementary Treatise on Statics. By J. W. Mulcaster F.R.A.S., Military Tutor. (London: Taylor and Francis.). THIS is a good book without any of that attempt at cramming, too common now in our elementary text-books. It is calculated to give the reader a good grasp of the elements of Statics. It goes over the usual ground, states and proves the principles well and clearly, and contains in each chapter a numerous and excellent series of examples. These examples consist of "graduated and classified groups of problems, each involving distinct statical principles." These, the author says, he finds, and our experience entirely agrees with his, make "an impression on the student's mind otherwise not attainable with problems indiscriminately taken." We gather from the book that it is the production of a good and practical teacher.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Aurora Borealis of Nov. 9 and 10

As the magnificent display of Aurora on the evening of the 10th was witnessed here under very favourable circumstances, and as several of its phases were of unusual occurrence, an abridged account may not be uninteresting.

The Northern Lights were first noticed at about 7.30 G.M.T., the appearance being that of a pale white light, which gradually rose from the N.N.W., until it completely enveloped the Great Bear, but was not sufficiently strong to hide even the faint star near Mizar. Towards 8.40 the auroral mist assumed the more definite form of three broad white bands, stretching across the sky from E. to W., the uppermost band lying just below Vega and Pollux.

At the same time a bank of dense black cloud rose from the N. horizon to the height of γ Ursa, and shot forth dark streamers as far as the upper arch of light. The streamers E. and W. were brighter than the central part, and waves of light moved slowly and at regular intervals from these brighter parts of the horizon, mingling together at the centre of the arch.

At 9.10 a very bright streamer made its appearance.

Up to this time the display had been colourless, but at 9.20 it assumed a greyish tinge, and had extended by 9.25 as far as β Cassiopeiae.

At 9.30 the western extremity of the arch was of a bright red colour, whilst only a slight appearance of redness was visible in the E.

The aurora then became wonderfully brilliant, and the rapidity of the changes surpassed anything that had been seen here for years. Flashes of light were succeeded by waves, and these in their turn by small detached clouds, which travelled rapidly across the sky. At 9.45 the waves and streamers seemed to converge to a point slightly S.E. of β Andromedæ.

In the square of Pegasus a curiously-formed cloud, in the shape of an enormous bird, suddenly appeared and disappeared several times, sending forth each time streams of light E. and W., as if from its outstretched wings.

At 10 the auroral light was strongest, and then the waves, moving rapidly from the N., appeared to return for a short distance on their path when they had passed a few degrees S. of the zenith, like waves breaking on the sea shore.

At 10.30 two distinct arches of light, the upper one passing through β Andromedæ, the lower one near Polaris, intersected each other E. and W. at an altitude of about 20°.

At 10.40 all colour had disappeared in the west, but a very brilliant red streamer stretched from the E. nearly to the Twins. About this time a thick cloud of elliptic shape was formed between the points N.W. by N. and W. Beneath this cloud was a pale auroral glare, and from its upper side a mass of broad dark streamers rose towards Polaris. At the E. end of the cloud a very broad streamer moved gradually westward, and shortly afterwards a similar streamer formed near the W. and moved in the same direction.

At 10.45 α Arietis was the centre, towards which the new violet-coloured streamers and the waves and flashes tended.

The last-mentioned cloud was then replaced by another similar in form, but situated farther from the E., its outer streamers of a yellowish green colour meeting in Cassiopeia.

At 11 the only colour visible was the violet in the W.

At 11.5 a point S. of γ Pegasi was the centre of motion.

At 11.15 the dark streamers were sharply defined, but extended only a few degrees above the cloud. Ten minutes later the stars below Vega and Ursa minor were completely hidden, and then from 11.25 to 12.15 the aurora gradually died away, leaving only a faint white glare on the N.W. horizon.

S. J. PERRY

Stonyhurst College Observatory

ON Friday evening, Nov. 10, I was fortunate enough to witness a brilliant display of the Aurora Borealis, which, if it did not surpass, certainly rivalled, that of Oct. 24, 1870.

At 9h. 20m. G.M.T. the whole sky was literally covered with auroral streaks to within 30° of the southern horizon, all apparently converging to a point near α Andromedæ. The streaks were of a white colour, having a slightly bluish tint (probably caused by the mass of intervening air), and their form, to within 15° of the point of convergence, was perfectly straight. The radial point was shown by an irregular mass of auroral light, from which bright streaks were spread out in every direction, those to the south being much shorter than the streaks to the north or west. The appearance of the sky at the time was that of the outstretched wing of an enormous bird. At 9h. 22m. a rich crimson glare was visible in the S.W., dividing the constellations Pegasus and Cygnus, and at 9h. 25m. a resplendent beam of white light 2° in width was conspicuous in the N.E.; its length was about 50°, and it was nearly parallel in direction with a line joining the stars α Capella and β Aurigæ, but 3° to the left of them. It remained visible for 5m.

At 9h. 25m. 30s. a white luminous meteor (apparently one of the " α Leonides") shot swiftly across the constellation Pisces, having a brightness = Sirius, duration 0.5sec., and length of path 10°, left no train or sparks.

At 9h. 32m. the constellation Perseus was overspread by a luminous glare of a reddish colour (known to dyers by the appellation of "ruddy brown," and which did not disappear for about 10m. At 9h. 34m. the crimson glow reappeared in the S.W. between Cygnus and Pegasus, thereby completing a gorgeous arch about 15° in width, extending from the S.W. to the N.E. horizon, passing over the constellations Cygnus, Lacerta, Perseus, Auriga, and Orion. This crimson belt divided the sky into two halves, that on the north being full of auroral streaks, two columns of which were very conspicuous in the north, passing over Ursa Major and extending nearly to the zenith. A small dark cloud lying horizontally across them divided them into two parts, each of which was distinctly visible.

At 9h. 40m. the streaks had entirely disappeared, being replaced by a diffused auroral glare, similar in appearance to the sky before dawn; but at 10h. the streamers reappeared with equal brilliancy. The radial point had now moved to 2° below β Andromedæ, and was now clearly pointed out by an irregular curve, or hook, about 4° or 5° in diameter, which, although observed at different times during the evening, was never completely formed, as 90° or 120° were always wanting to form a complete circle.

At 10h. 23m. a curious phenomenon presented itself. A small irregular patch of crimson light, about twice the diameter of the moon, appeared over β Trianguli, which slowly, and gradually expanded, but after a lapse of about 30s. (when about 15° in diameter), its colour changed to the ordinary bluish white of the aurora, the phenomenon lasting altogether about 2m. At 10h. 25m. a broad greenish white band appeared in the N.E.

By this time the centre of convergence had reached β Trianguli, thus showing apparent progressive motion towards the east at the rate of about 15° per hour (which is the rate of the rotation of the earth upon its axis). It is worthy of notice that in the auroral displays of October 1870 the same stars formed the radiant, and its motion was in the same direction.

At 10h. 37m. a beautiful crimson beam appeared in Auriga (in the same position previously occupied by the white streak at 9h. 35m.). Its length was about 40°, and at 10h. 50m. a gorgeous triple streak was visible in the same position, which presented the appearance of a broad crimson ribbon, with a border of white on each side. In about five minutes it faded out of sight.

At 11 o'clock the auroral light was again diffused over the whole northern sky, bounded on the south by a bright milky

arch extending from the E. to the S.W. by S. horizon, visible for ten minutes.

At 11h. 30m. only a few faint streamers, and at 12 o'clock the arch was again visible to the S.E., but aurora very faint.

During the progress of the display the peculiar undulatory phases noticed last year were particularly observed. The waves of light seemed to chase each other in rapid succession along the radiating streaks, coming into collision at the point of convergence. The semicircular masses surrounding this point appearing as if they occupied a *fixed* position in the sky, and becoming visible to the eye only as the intermittent waves reached them, somewhat analogous to the waves of the ocean dashed against a rock and breaking over it in a mass of white foam.

In conclusion may I venture to suggest the application of photography to auroral phenomena; and perhaps some of your readers might *practically* answer the query, "Can a photograph be taken of an auroral display?"

ROBERT MCCLURE

342, Argyle Street, Glasgow, Nov. 11

THERE was a brilliant display of Aurora Borealis here on the evenings of Thursday and Friday, November 9 and 10—especially the latter night. Towards 9 o'clock a hazy light began to spread itself over the northern sky, near the horizon, not unlike a brilliant twilight. At 8 p.m. two arches were quite distinct, the upper one being well defined, with its apex passing through the head of Ursa Major. Gradually streamers began to pass from this, and by 9h. 15m. the scene was simply gorgeous. I do not remember ever seeing the streamers so expanded—more like flames, nor possessing such intense whiteness, so much so, that the evening was almost as light as if the moon had been shining. After proceeding from the upper arch, their course was most rapid to the zenith—apparently passing at times behind clouds, then suddenly emerging—where a magnificent whirling motion was formed, which kept changing in true Protean fashion. A grand, though somewhat dingy, red haze next appeared in the west, which gradually ascended towards the zenith, when it disappeared. Meanwhile flashes of light, resembling summer lightning, darted upwards from about 45° from all directions, and not least from the south—the N.W. heavens assuming a muddy green colour. About a quarter-past ten p.m. the aurora gradually diminished, especially the upper arch, and streamers from it. Then the lower arch began to give off streamers, but these were short and of short duration, though of considerable brightness. The display of Friday, if it fell short of those of October 23 and 24, 1870, in point of brilliant colours, surpassed them in some respects—e.g. extent of streamers, and brilliancy of light. Barometer corrected and reduced 29.172; Temperature 32°. THOMAS FAWCETT

Blencowe School, Cumberland

THERE was a very bright Aurora here last night: the streamers were white, with a red glow in some places. At about ten there was that beautiful and rare phenomenon—a "corona" of streamers converging at the zenith. The barometer was about 29.6. This morning is fine, with the barometer rising.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Nov. 11

THERE have been two magnificent auroral displays on the nights of the 9th and 10th inst. That on the 9th commenced at 10 o'clock, and continued with little interruption until 12.45; and last night from 9.40 until 12 o'clock. Both displays were in the north and north-west, and at times the streamers reached the zenith, but I did not observe them to pass beyond that point. The colours were varied; at one time of a beautiful crimson, at another a greenish white. Last night's display was the most interesting, but not so brilliant as that of the previous night. The aurora made its first appearance by an undefined redness in the north; it then gradually developed into a crimson, and assumed the shape of a vertical pillar, the upper part tapering to a clearly defined point, within a few degrees of the zenith. It remained in this shape and position for two minutes, and then faded away. At 10.15 there appeared, at about 10 degrees above the horizon, a peculiar lightness, like the edge of a dark horizontal cloud illuminated by the hidden moon, but I could distinctly discern some stars below the illuminated *stratum*, which proves that the cloud was transparent; the stars could not, however, be seen through the lightness. At 10.40 there were three distinct streamers

shooting up from this light, emanating from separate parts, but all in the north and north-west. They then assumed an easterly movement, the right hand streamer before disappearing being in the north-east. The centre one of these was of a very light colour, approaching a faint or whitish green; the others were crimson. At 11 o'clock I saw an exceedingly brilliant *patch* undefined in the north-east; by this time some clouds, stratified horizontally, rose from the northern horizon and passed into the light part of the heavens, which seemed to influence the display by intensifying the streamers, which were shooting up, at this time, to the zenith. At 11.30 I saw six beams start across east and west, of a whitish colour with dark spaces between, and the southern one in the zenith. The northern streamer now disappeared, but the *auroral twilight* was still visible, although gradually fading, and by 12 o'clock all was darkness. I did not continue my observation beyond this hour, the temperature not being conducive to personal comfort.

I may remark that with the exception of the few clouds which rose last night, both nights were perfectly cloudless, and the milky way shone with uncommon splendour. A portion of this band of stars at one time looked grand, as one mighty streamer ran along its course, some of the largest stars being visible through the intercepting redness.

I hope that some of your correspondents will give particulars of any magnetic disturbances which may have occurred on the nights of the above displays.

JOHN JEREMIAH

43, Red Lion Street, Nov. 11

P.S.—I have been informed that the white horizontal light mentioned in my communication of the 11th inst. was visible at 7.30 on the night of the 9th, but no streamers were seen until the time stated by me.

On Saturday night, at 7.45, I saw in the north-western sky a slight auroral redness, but it did not last more than two minutes.

Nov. 13

J. J.

Nov. 10th, 11 p.m.—I have just witnessed a most magnificent display of Aurora. I first saw it at 9.30. Here is an account of it. The bearings given are magnetic.

9.30 p.m.—On the W. was a deep crimson glow of the richest possible colour, about 50° broad and 60° high. From W.N.W. to N. the sky was filled by a mass of white light, pulsating in long horizontal masses moving upwards. At 9.36 they were moving, not very uniformly, at the rate of 33 waves per minute. From the N. to the E. extended a bright horizontal band of steady white light, marked with vertical lines and having jagged edges. Suddenly from the centre of it shot up a vertical white streamer 3" or 4" wide; this remained stationary for a few minutes and then gradually faded away.

At 9.38 a fan-shaped mass of white light appeared at N.N.E. At 9.45 a band of white light extending from the horizon to a height of about 20°. From the centre of this streamed upwards a kind of waving flag of intense red light, about 20° broad and reaching to the zenith. At N.N.E. the fan was gone and a bright horizontal band of white light marked with vertical lines had taken its place. It was almost 40° long and 30° high. At 9.50 there appeared an arch of white light about 10° thick. The centre was about 60° high, white, the ends were on the horizon at E.N.E. and N.W. This vanished and was replaced by a horizontal white band, about 60° long and 10° high, the lower edge being about 20° above the horizon. Out of this presently rose four beautiful white streamers. At 9.52 an intensely bright red light was observed at W. At the N.E. were a few patches of white light. At the N.N.E. appeared about ten vertical white streaks for a minute or so. They were 15° high and filled a horizontal space of about 20°. At 9.53 a rather fine meteorite fell. At the N.W. was a red stream about 30° broad and 80° high, while at W.S.W. was a mass of red light. At 9.55 the mass of white light at E.N.E. threw out a number of jets of light in shape like the streams of water from the rose of a watering can. At 10 p.m. the arch which had vanished re-appeared, reaching from W.N.W. to E.N.E. It glowed with a deep white light, which was motionless, except that at 10.2 I observed two downward waves. At 10.3 a long streamer grew out of it. At 10.5 the right-hand end was tossed up into the form of a haystack. At 10.8 a glow spread upwards from the centre of the arch, and filled the upper part of the sky. At the same time a slight patch of red light reappeared in the W. The sky to the S. was lighted up with the reflection of the white light in the N. The reflected light seemed to have a faint reddish tinge.

By 10.10 nothing was left except the arch, and between 10.10 and 11 that also vanished.

The stars could be seen distinctly through the aurora. When the light was at the brightest I could see the figures and hands of a large watch, but could not distinguish the figures one from another. Thermometer 30° F.; Barometer 29.69 inches.

Pixholme, Dorking, Surrey J. E. II. GORDON

Structure of Lepidodendron

PROFESSOR DYER has already discovered one of the many new facts with which he has yet to become familiar, and hastens, in a straightforward manner, to acknowledge the circumstance; but I must again remind him that this, along with many other facts, was described in No. 129 of the Proceedings of the Royal Society. Professor Dyer further says: "Suppose the transverse septa separating these cells absorbed, as *probably eventually they would have been*, and the rows of cells become scalariform vessels." But I can assure him, as a question of fact, that these cells do *not* become so changed; consequently his conclusion that the central cells and the investing vessels are but parts of "one central structure" becomes negatived. The separation of these two structures *increases* with age instead of *diminishing*.

W. C. WILLIAMSON

Encke's Comet

It may interest those who possess small telescopes to know that this comet is now within the range of instruments of moderate apertures. On November 10 I had a very satisfactory view of it, with a 4" equatorial by Cooke; no signs of a nucleus were observed, but there appeared to be a slight condensation of light on the following side of the comet.

THOS. G. E. ELGER

Bedford, Nov. 11

The Science and Art Department

In your last number there appears a letter signed "Henry Uhlgren," which, among other interesting statements, contains the following: Referring to Mr. Forster's statement in the House of Commons that there was no foundation for the report that "the Examiners after having made their reports had the papers returned to them, with an instruction to reduce the number of successful candidates, as an intimation had been given by a right hon. gentleman that the amount of the Grant due upon those papers must be reduced 20,000l.," Mr. Uhlgren states: "But previous to that a provincial local secretary, hearing the rumour, wrote to ask the Department if it were true, and received a reply saying it was true, and that instead of the amount being 20,000l. it was 40,000l. (the Department's letter can be produced.)" Premising that the amount of the whole vote for payments to teachers on results in science (which was to be reduced by 40,000l.) was 26,000l., may I ask for the production or publication of this extraordinary official letter?

X

ECONOMICAL ALIMENTATION

IN glancing over the recent issues of the *Comptes Rendus*, one cannot but fail to be struck with the practical importance of many of the communications contained therein, a large proportion of which bear special reference to the Siege of Paris. In nearly every branch of science there is some endeavour made to supplement and improve our knowledge in matters such as were then of the greatest importance, and the members of the *Académie* have come forward eagerly to aid, by advice and precept, in overcoming the misery of a prolonged siege. Unfortunately, but little could be done, even by such men as Fremy, Dumas, Chevreul, and others, against the insuperable difficulties which presented themselves; but nevertheless Paris owes much to her men of science who contributed many services of value, at a time when these were most needed. The manufacture and employment of nitro-glycerine in mines and shells, were successfully accomplished at a crisis when the stock of gunpowder was running terribly short, and the supply of some other reliable explosive was rendered imperative. Hitherto nitro-glycerine had been regarded as a most dangerous combustible, liable to explode at the slightest concussion, and yet we hear of its employment in shells against the Prussians, thundered forth from guns of the

heaviest calibre, without one single instance of its premature explosion being recorded. Again the question of ballooning, although not perhaps very far advanced by the deliberations of the *Académie*, has, at any rate, been more satisfactorily solved than at any previous period, and Paris has been certainly the first to employ these frail and romantic contrivances in a practical every-day manner, and thus to render the words, "*par ballon monté*" familiar to the ear as a household phrase. In matters of surgery, as in those of a sanitary nature, sound advice was not wanting, and even the abstract calling of the soldier, —the philosophy of his manner of fighting—formed the theme of much scientific discussion.

But the most interesting, perhaps, of all the subjects with which the *Académie des Sciences* busied itself, was that of seeking an economical means of alimination for the inhabitants of Paris during the siege. Given certain limited sources of supply, a fixed amount of suitable organic matter, and the problem was how to use the same to the fullest and most profitable degree. Of sheep and oxen there was but an exceedingly limited provision in proportion to the very populous state of the city, and although corn and wine were said to be in abundance, there is no doubt the authorities were from the first sorely troubled by the vague estimates that were published of these comestibles.

As a suitable manner of economising corn, M. Gauldrée called attention to the method in vogue among the Romans of parching and bruising the grains, which in this state may be made to yield an excellent and highly nutritious soup or porridge. The corn is carefully sifted by hand, browned without charring, until it breaks when taken between the teeth, and then ground in any available mill; it is mixed with cold water, boiled for thirty minutes, and seasoned as desired. So economical was this preparation, that at the public kitchens, established in certain quarters of Paris, it was possible to dispense one portion of *bouillie romaine* together with a small modicum of wine for the amount of five centimes.

A proposition to manufacture artificial milk, brought forward by M. Gaudin, seems worthy of some notice. That gentleman estimated that 500,000 litres per day of milk could be prepared in Paris at an exceedingly trifling cost, which should have all the nutritious qualities of good milk, and which should, besides, be neither unpleasant of taste or smell. An emulsion at a very high temperature is made of *bouillon de viande* prepared from bones, fat, and gelatine, and when cold, a product is obtained resembling in taste stale milk of a cheesy flavour; the components of ordinary milk are all present, the gelatine representing the casein; fat, the butter; and sugar, the sugar of milk. For admixture with coffee, chocolate, soup, &c., the milk is said to be by no means disagreeable.

Many propositions were brought forward to economise the blood from the abattoir, the plan suggested by M. Gautier of mixing it with flour in the manufacture of bread being perhaps the best and simplest, as the fibrine and albumen, so rich in nitrogen—of which the alimentary properties are well known—are in this way utilised to the highest degree. Less inviting is the proposal of M. Fud to consume the carcasses of animals that died of typhus, rhinderpest, and other diseases, the flesh in these instances being, so asserts M. Fud, capable of use as food, if only cooked in a suitable manner.

More important, however, than all, is M. Fremy's attempt to bring forward osseine as an article of food. Osseine is essentially different from gelatine, which has recently been asserted by chemists—erroneously, so M. Fremy thinks—to be not only unnutritious, but positively injurious to the human system. Leaving, however, the question of gelatine on one side, M. Fremy proceeds to advance the qualifications of osseine as an alimentary substance. Although gelatine and osseine are isomeric, in the same way as starch and dextrine are isomeric, they

have not the same properties. Gelatine, unlike osseine, does not exist in organism, but is produced by chemical transformation resulting from the action of water and heat upon the bony tissue; gelatine, moreover, is completely soluble in water, while osseine is not so. For these reasons the two substances would doubtless be different in their alimentary capacities, and deductions drawn from the influence of one upon the human system ought not in any way to prejudice the other. Of course, says M. Fremy, osseine cannot be expected to fulfil the same duty as a complete aliment; such, for instance, as bread, or meat, but must be employed in conjunction with some other suitable material. In the same way gluten, which is simply flour freed from starch, oil, and soluble substances, would alone be powerless to support life and health. If regarded in the same light as fibrine, casein, and albumen, and associated with other bodies, osseine would be found a valuable aliment. White meat, calf's head, neat'sfoot, &c., contain much bony tissue, and their nutritious qualities are incontestable.

Of this osseine, then, bones are said to contain 35 per cent., the mode of separation being simply to slice the bone very thinly, and to treat the same with dilute hydrochloric acid; hard white bones, free from fat, are most suitable, and some care and attention in manipulation is of course necessary, so that the product may be perfectly sweet and free from any taint or unpleasant odour. For if disgust is once aroused against this kind of food, as indeed against any other for that matter, no amount of pushing or puffing can force it into the public market. Should, therefore, any trace of acid be perceptible after preparation of the osseine, it is recommended that the product be treated with an alkali of some kind, for example, lime or carbonate of soda, but this must obviously be done with due care and discretion. The cost of this aliment is about one franc per pound, whereas gelatine of good quality costs from four to five francs.

As regards the best method of cooking or curing, M. Fremy recommends the swelling of the mass with hot water, and then boiling for about an hour, when the tissue becomes soft and pliable; it may be seasoned in the cooking, or may be allowed to cool and then kept for thirty-six hours in brine. If eaten warm with admixture of some fat and vegetables the osseine is decidedly palatable. Owing to its large constituent of nitrogen it is extremely nutritious, and, furthermore, forms a comestible not liable to become putrid.

It is right to mention that on some of the points enumerated by M. Fremy, exception is taken by M. Dumas and others, who are not so confident of the real value of osseine as an alimentary substance, those gentlemen maintaining the injurious nature of gelatine; M. Chevreul, however, confirms to some extent M. Fremy, and states that osseine is decidedly more nutritious than gelatine.

Other measures for improving the alimentation of Paris were taken during the siege, but these for the most part present little novelty. Mr. Wilson's plan for salting the carcasses intact, and thus preserving the meat in an almost fresh condition, was resorted to, that gentleman bringing his personal staff from Ireland to afford assistance just at the instant of closing the gates of the metropolis. The assistance of M. Georges, whose plan of preserving meat is both original and peculiar, was likewise obtained; this invention, which has been practised it is said with much success in America, is adapted more particularly for the curing of mutton rather than beef, and consists in treating the meat in a bath acidified with hydrochloric acid, and afterwards in a solution of sulphate of soda. In this condition, after further sprinkling with sulphate of soda, the flesh is packed in tins and soldered down: the sulphate of soda acting upon the hydrochloric acid gives rise to sea salt and sulphurous acid, thus ensuring the perfect preservation of the meat.

THE TEMPERATURE PRODUCED BY SOLAR RADIATION

SIR ISAAC NEWTON determined the intensity of solar radiation by observing the increment of temperature of dry earth on being exposed to the sun. In the latitude of London at midsummer, dry earth acquires a temperature of 150° in the sun at noon and 85° in the shade, difference about 65° Fah. This difference Sir Isaac Newton regarded as a true index of the intensity of solar radiation; hence his celebrated demonstration proving that the comet of 1680 was subjected to a temperature 7,000 times higher than that of boiling water ($212^{\circ} \times 7,000 = 1,484,000^{\circ}$ Fah.).* The comet when in its perihelion being within one-third part of the radius of the sun from his surface, we have to add the diminution of temperature, 0.44 , attending the dispersion of the rays in passing through the solar atmosphere and the remainder of the stated distance from the sun. Accordingly, the demonstration showing that the comet of 1680 was subjected to a temperature 7,000 times higher than that of boiling water, establishes a solar temperature exceeding $2,640,000^{\circ}$; and if we add 0.21 for the retardation of the rays in traversing the terrestrial atmosphere, it will be found that the temperature deduced from the experiments with incandescent radiators, and our actinometer observations, differs scarcely $\frac{1}{2}$ from that roughly estimated by the author of the "Principia." In order to comprehend fully the merits of the method of determining solar intensity conceived by his master mind, let us imagine an extended surface of dry earth, one half of which is shaded, the other half being exposed to the sun. Dry earth being a powerful absorbent and radiator, and at the same time a bad conductor, the central portion of the supposed surface evidently cannot suffer any loss of heat by lateral radiation; while the non-conducting property of the material prevents loss by conduction laterally or downwards. Consequently, no reduction of temperature can take place excepting by radiation in the direction of the source of the heat. Removing the shade, during an investigation, it will be found that, notwithstanding the uninterrupted radiation of the exposed substance upwards, the intensity will gradually increase until an additional temperature of about 65° Fah. has been acquired. Indisputably, this increase of temperature is due to unaided solar radiation. Evidently the accidental interference of currents of air need not be considered. Besides, if the dry earth is confined within a vacuum, such interference may be entirely obviated. It is scarcely necessary to point out that the generally-adopted mode of measuring the sun's radiant heat by thermometers, is in direct opposition to the principle involved in the method under consideration. The meteorologist, in place of preventing the bulb from radiating in all directions and guarding against loss of heat by convection, puts his thermometer on the grass, or suspends it on a post, one half of the convex area of the bulb receiving the sun's radiant heat, while the other half is permitted to radiate freely, the whole being exposed to the radiation from surrounding objects and to the refrigerating influence of accidental currents of air, in addition to the permanent current produced by the ascending heated column above the bulb. This explains the cause of the perplexing discrepancies in meteorological records. The extent of the diminution of intensity of solar radiation occasioned by cold air acting on the bulb, and by the latter radiating freely in all directions, is demonstrated in the most conclusive manner by the result of observations made with the instrument described by Père Secchi in

* Sir Isaac Newton has been criticised for comparing the temperature to that of red-hot iron, "A term of comparison indeed of a very vague description," it is said in "Outlines of Astronomy." This criticism is far from being correct, since the demonstration clearly shows what is meant by the term red-hot, viz. a temperature, 25 times that of boiling water. The reference to red-hot, exceeded "two thousand times," was evidently intended to furnish some adequate notion of the inconceivably high degree of temperature involved in the computation.

his recent work "Le Soleil" (p. 267). "During a great number of observations made at Rome," says the author, "the difference between the two temperatures (that indicated by the thermometer exposed to the sun and that of the surrounding casing), was $12^{\circ}06'$ ($21^{\circ}70'$ Fah.); during days when the sky was clearer, it rose to $14'$." Consequently, the highest temperature indicated by the instrument referred to, was $25^{\circ}2'$ Fah., against $66^{\circ}04'$, which is the true maximum solar intensity in the latitude of Rome. It will be seen then, that, by exposing the bulb of the thermometer in the manner pointed out, it is possible to reduce the temperature produced by solar radiation to $0^{\circ}38$ of the actual temperature.

It will be proper to observe with reference to the accompanying tables—constructed in accordance with the result of investigations continued winter and summer during three years—that the opinion expressed by the Director of the Roman Observatory, respecting solar intensity at different seasons, is wholly at variance with the facts established by my numerous observations. The question was raised last summer whether the high temperature during the "heated term" would not charge the atmosphere with an additional amount of vapour capable of retarding the passage of the heat rays, thus rendering the figures entered in my tables to some extent unreliable. Accordingly, during the solstice June 26, 1871, the sky being very clear, the actinometer was put in operation for the purpose of ascertaining with critical nicety whether the atmosphere which had been loaded with vapour for several weeks previously possessed any unusual property tending to check the heating power of the sun's rays. The observations were made late in the afternoon under great zenith distance and increased atmospheric depth, in order to subject the heat rays to an additional retardation from the supposed vapours. The result is recorded in Table C, by which it will be seen that the reduction of temperature was only $0^{\circ}26'$ Fah., a difference too small to call for any explanation. The result of the observations made during midwinter are equally conclusive with reference to the permanency of solar energy at all seasons. Among others may be mentioned that of January 17, 1871, the zenith distance being $61^{\circ}30'$, the actinometer remained perfectly stationary at $58^{\circ}73'$ Fah., from 12h. 10m. to 12h. 20m. P.M. The table just referred to shows that on June 26, 1871, the actinometer indicated $53^{\circ}08'$ when the sun's zenith distance was $61^{\circ}30'$. Hence during midwinter the temperature proved to be $58^{\circ}73' - 53^{\circ}08' = 5^{\circ}65'$ higher, for corresponding zenith distance, than during the summer solstice. By reference to Table B it will be seen that owing to the diminished distance between the sun and the earth, the increment of temperature on January 17, ought to have been $5^{\circ}75'$, discrepancy = $0^{\circ}1'$ Fah. In the face of such facts it is idle to contend that the temperature produced by solar radiation under corresponding zenith distance and a *clear sky*, varies from any other cause than the varying distance between the sun and the earth. Of course there are many regions in which the sun, in consequence of local peculiarities, but seldom acts with maximum energy. Alaska, for instance, is hardly ever favoured with a full amount of solar heat; nor does Rome, we are now informed by the Italian physicist, receive maximum solar heat excepting during winter, owing, it may be imagined, to the absorptive power of the atmosphere of the Campagna during summer.

Without entering the field of speculation, let us consider that the established diminution of solar heat on the ecliptic, nearly 18° Fah., proves the existence of a powerful retarding medium, and points to the presence of a permanent mass of aqueous matter in the higher regions of the atmosphere; necessary, it may be urged, to regulate terrestrial temperature and render vegetable life possible under the destructive vicissitudes of heat and cold, inevitable in the absence of a permanent regulator. The assumption that the supposed mass of aqueous

matter is nearly invariable, and at all times present, can alone account satisfactorily for the remarkable fact that, whenever a clear sun is presented, either by the opening of the clouds or by their disappearance, the actinometer indicates the same temperature, subject only to the variations depending on the sun's zenith distance, and the varying position of the earth in its orbit. The variation of temperature produced by the latter cause is entered in Table B, for every fifth day in each month. This table, an extract from a more elaborate one showing the temperature for every day in the year, the meteorologist will find indispensable to harmonise observations made at different seasons. It may be mentioned that the attempt to construct a curve, the ordinates of which would determine the temperature for different zenith distances, at first met with apparently insuperable difficulty. The result of observations made at different seasons under the most favourable circumstances, failed to produce a regular curve until the change of temperature corresponding with the varying distance between the sun and the earth was determined and introduced in the calculation. This at once harmonised the previously conflicting observations, and rendered the task easy of perfecting the curve, and obtaining ordinates consistent with the observed temperature produced by solar radiation at different seasons and different zenith distance.

Regarding Table A, it will suffice to state that it is based upon our acquired knowledge of the temperature produced by solar radiation at given zenith distances when the earth is in aphelion. Evidently if we know that, for instance, when the sun's zenith distance is 43° the temperature is $60^{\circ}57'$ Fah., we know also that this is the temperature at noon on the Arctic Circle, the latter being 43° from the ecliptic at the summer solstice. Again, the North Pole being $66^{\circ}30'$ from the ecliptic at the same time, we find by referring to the figures entered in the table of zenith distances and temperatures (previously published) that the depth of atmosphere to be penetrated by the rays when the sun is $66^{\circ}30'$ from the zenith, is 2,444 times greater than on the ecliptic; and that, therefore, the radiant intensity, as shown in the table, is reduced from $67^{\circ}20'$ at the tropic of Cancer to $49^{\circ}91'$ Fah. at the pole. Possibly it may be found necessary to introduce a correction for the difference of atmospheric density in the higher latitudes; but at present I deem it inexpedient to complicate the matter by applying a correction which obviously cannot affect the general result.

J. ERICSSON

NOTES

THE Anniversary Meeting of the Royal Society will be held on the 30th inst., when Sir Edward Sabine will deliver his eleventh and last anniversary address. Prof. G. B. Airy, the Astronomer Royal, will be brought forward as his successor.

AT the opening meeting for the session of the Royal Geographical Society, on Monday evening last, the president, Sir II. Rawlinson, announced that, in consideration of Dr. Livingstone's services, Her Majesty's Government had been pleased to grant to his children the sum of 300l.

THE following are the lecture arrangements for 1871-72 at the Royal Institution, Albemarle Street:—Prof. Tyndall, F.R.S.: six lectures on "Ice, Water, and Air," on December 23, 30, 1871; January 2, 4, 6, 9, 1872. Dr. W. Rutherford, F.R.S.E.: ten lectures on "The Nervous and Circulatory System," on Tuesdays, January 16 to March 19. Prof. Odling, F.R.S.: ten lectures on "The Chemistry of Alkalies and Alkali Manufacture," on Thursdays, January 11 to March 21. Mr. W. G. Clark, late Public Orator: six lectures on "The History of Dramatic Literature, Ancient and Modern," on Saturdays, January 20 to Feb. 24. Mr. Moncreu D. Conway: four

lectures on "Demonology," on Saturdays, March 2 to 23. The Friday evening meetings will commence on January 13: The Friday evening discourses before Easter will probably be given by Mr. W. R. Grove, the Archbishop of Westminster, Professors Odling and Humphrey, Dr. Gladstone, Messrs. C. W. Siemens, R. Liebreich, and John Evans, and Prof. Tyndall. Dr. Wm. A. Guy, F.R.S.: three lectures on "Statistics, Social Science, and Political Economy," on Tuesdays, April 9, 16, and 23. Mr. Edward B. Tylor, F.R.S.: six lectures on "The Development of Belief and Custom amongst the Lower Races of Mankind," on Tuesdays, April 30 to June 4. Prof. Tyndall, F.R.S.: nine lectures, on Thursdays, April 11 to June 6. Mr. R. A. Proctor, F.R.A.S.: five lectures on "Star Depths," on Saturdays, April 13 to May 11. Prof. Roscoe, F.R.S.: four lectures on "The Chemical Action of Light," on Saturdays, May 18 to June 8.

The following Lectures to Women, on the Elements of Physical Science, will be delivered during the ensuing term, in the Lecture Theatre of the South Kensington Museum, by Professors Huxley, Guthrie, and Duncan. Professor Duncan: ten lectures on "Elementary Physiography," commencing on Saturday the 18th November, and ending on the 20th December; Saturdays and Wednesdays at 2.30. Professor Guthrie: fifteen lectures on "Elementary Physics and Chemistry," commencing on Wednesday the 10th January, and ending on Wednesday the 28th February; Wednesdays and Saturdays, at 2.30. Professor Huxley: ten lectures on "Elementary Biology," commencing on Saturday the 2nd March, and continued on Saturdays only at 2.30 P.M., on the 9th, 16th, 23rd March; 13th, 20th, 27th April; 4th, 11th, 18th May.

A CLASS for the teaching of Natural Science has been formed at the College for Women, at Hitchin. Until very recently, classics and mathematics were almost exclusively the subjects brought under the consideration of the students; but a demand for the teaching of Natural Science has arisen, and under the advice of Prof. Living, of Cambridge, the subject of Chemistry has been taken to begin with. Prof. Living is on the list of lecturers at the College for Women, but in consequence of the weak state of his health—the result of overwork—he is unable to undertake the teaching himself. The actual professor at Hitchin is Mr. Hicks, Natural Science Lecturer at Sidney Sussex College, Cambridge. The lecturer gives one lecture a week, illustrated by experiments; and Mrs. Whelpdale, a lady who has had experience in teaching the subject, also gives supplementary teaching once a week. This lady works under the direction of Mr. Hicks, and acts as a tutor preparing for the lectures. So far as this has been worked, the plan seems to answer exceedingly well. The apparatus considered by Prof. Living and Mr. Hicks to be indispensable, has been provided by the college, but the authorities would be glad to make it more complete. Prof. Living has kindly promised to lend from Cambridge some of the more expensive things which are not in constant use. It is quite evident, however, that until there is a completely furnished laboratory, with all the appliances requisite for the study of Physical Science, the efforts made for the teaching of such science must be, to a certain extent, partial. It is to be hoped that funds will be forthcoming from some of the friends of the higher education of women to furnish the means for all that is needed in the new college building near Cambridge, to which the College for Women will, in time, be removed.

A BARONETCY has been conferred on Prof. Christison of Edinburgh in recognition of his well-earned position at the head of the profession in Scotland. Prof. Christison already holds the appointment of Honorary Physician to the Queen in Scotland, and is President of the Royal Society of Edinburgh. He has received the honorary doctorate of Oxford, and has been twice

President of the Royal College of Physicians of Edinburgh. He has been a professor of the University of Edinburgh since 1822, and is the author of a work on Poisons, which, although written many years since, is still a standard authority; and of a highly esteemed treatise on *Materia Medica*. Sir Robert Christison is a Crown Member of the General Medical Council, and took a leading part in framing the authorised edition of the *British Pharmacopoeia* issued by the Council. Recently, as a mark of especial esteem and respect from his colleagues in the University of Edinburgh and other friends, his bust was sculptured by subscription, and placed in the library of the University—an honour which, according to the *British Medical Journal*, had not previously been conferred on any professor during life.

In the year 1872 there will be open for competition, at St. John's College, Cambridge, four minor scholarships, two of the value of 70*l.* per annum, and two of 50*l.* per annum, together with three exhibitions of 50*l.* per annum, tenable on the same terms as the minor scholarships, and two of 40*l.* per annum, tenable for four years. The examination of candidates for the above-mentioned scholarships and exhibitions will commence on Tuesday, the 9th of April, 1872. The examination will consist of three mathematical papers and four classical papers. Besides the nine minor scholarships or exhibitions above mentioned, there will be for competition an exhibition of 50*l.* per annum for proficiency in natural science, the exhibition to be tenable for three years in case the exhibitor has passed within two years the previous examination as required for candidates for honours, otherwise the exhibition to cease at the end of two years. The candidates for the Natural Science Exhibition will have a special examination on Friday and Saturday, the 12th and 13th of April, 1872, in (1) chemistry, including practical work in the laboratory; (2) physics, viz., electricity, heat, and light; (3) physiology. They will also have the opportunity of being examined in one or more of the following subjects—(4) geology, (5) anatomy, (6) botany, provided that they give notice of the subjects in which they wish to be examined four weeks prior to the examination. No candidate will be examined in more than three of these six subjects, whereof one at least must be chosen from the former group. It is the wish of the master and seniors that excellence in some single department should be specially regarded by the candidates. Candidates must send their names to one of the tutors (Rev. S. Parkinson, Rev. T. G. Bonney, and Mr. J. E. Sandys), fourteen days before the commencement of the examination. The minor scholarships are open to all persons under twenty years of age, whether students in the university or not, who have not yet commenced residence in the university or who are in the first term of their residence.

TRINITY COLLEGE, Cambridge, offers one or more of its foundation scholarships, of the value of 80*l.* per annum each, for proficiency in the Natural Sciences. The examination will commence on April 5, and will be open to all undergraduates of Cambridge or Oxford, as well as to persons, under twenty-one, who are not members of the Universities. Further information may be obtained from the Rev. E. Blore, tutor of the college.

THE first course of Cantor Lectures of the Society of Arts for the ensuing session will be "On the Manufacture and Refining of Sugar," by C. Haughton Gill, and will consist of four lectures to be delivered Monday evenings November 27, and December 4, 11, and 18.

At the late examination for the Natural Science Moderatorship in Trinity College, Dublin, the first senior moderatorship was awarded to Phineas Simon Abraham, the second to Charles B. Ball; the junior moderatorships were given to R. D. Purefoy and W. J. Smyly. The subjects for examination were—Comparative and Physiological Anatomy, Zoology, Botany, Physical Geography, and Palaeontology.

THE annual general meeting of the Royal Horticultural Society of Ireland was held in Dublin on the 9th of November. The report of the Council was most satisfactory, and the treasurer's account showed a balance on the year to the credit of the society of upwards of 1,060*l.* Of this sum 1,000*l.* was added to the reserve fund. In addition to the usual early Spring, Summer, and Autumn shows it was resolved to hold in October next a grand international fruit show, which we hope will be attended with success.

MR. JOHN RUSKIN has lately presented a valuable collection of minerals and fossils to the High School, Nottingham. Among the former are two hundred metalliferous ores, including some rare specimens from Hungary, a hundred choice silicates, the principal varieties of fluor spar, calcite, and barytes, some agates, and a series of fine gems. The fossils are mainly from the Cretaceous Rocks of Kent and Sussex.

ON Saturday last Sir William Stirling Maxwell was elected Rector of the University of Edinburgh.

THE great Aquarium at the Crystal Palace, of which we recently gave a full description and drawing, was formally opened to the public on Friday evening last by a *soirée*.

THE Session of the Institution of Civil Engineers commenced on the 14th inst., and the annual general meeting "to receive and deliberate upon the report of the Council on the state of the Institution, and to elect the officers for the ensuing year," will be held on Tuesday, the 19th of December. At the same time the members have been reminded of the obligation entered into on election to promote the public and scientific obligations contemplated in the Royal Charter of Incorporation granted to the institution by preparing, or aiding in the preparation of, original communications for reading at the meetings, by frequent attendance at the meetings and occasionally taking part in the discussion, and by presenting to the library copies of reports and scientific treatises not already in the collection. It has also been notified that the qualifications of candidates seeking admission into the institution must in all cases be set forth with the utmost precision and in considerable detail, in order to enable the Council, upon whom the classification involves, and the members, with whom the subsequent election rests, to form a correct opinion as to the nature of the practice, the extent of the experience, and the degree of responsibility of every candidate. The casualties which have occurred among the members of this body during the last three months include the death of Field-Marshal Sir John Burgoyne, G.C.B., &c., honorary member; of Messrs. Joseph Hamilton Beattie, John George Blackburne, Robert Benson Dockray, Albinus Martin, and Josiah Parkes, members; and of Messrs. Arthur Field, Edward Mosely Perkins, and Henry Beadon Rotton, associates. This has reduced the total number of members of all classes from 2,009, at which it stood on the 1st of August last, to 2,000, comprising 14 honorary members, 725 members, 1,056 associates, and 205 students. During the period referred to the ordinary general meetings have been suspended, so that there has been no ballot for new members.

MR. BROTHERS has made a photograph eight inches in diameter of one of Mr. Proctor's star maps, containing nearly fifty thousand stars. The more marked constellations are just distinguishable upon a background, which appears to be shaded with innumerable minute points representing smaller stars. The increase of intensity in the shading is very evident upon certain parts of the picture. The whole represents the heavens as we should see them if the pupils of our eyes were a little more than two inches in diameter.

DR. J. B. PETTIGREW, F.R.S., will deliver a course of twelve lectures on physiological and pathological subjects at the Royal College of Surgeons, Edinburgh.

THE GEOGNOSY OF THE APPALACHIANS AND THE ORIGIN OF CRYSTALLINE ROCKS*

III.

THE direct formation of the crystalline schists from an aqueous magma is a notion which belongs to an early period in geological theory. De la Beche, in 1834,[†] conceived that they were thrown down as chemical deposits from the waters of the heated ocean, after its reaction on the crust of the cooling globe, and before the appearance of organic life. This view was revived by Daubrée in 1860. Having sought to explain the alteration of palæozoic strata of mechanical origin, by the action of heated waters, he proceeds to discuss the origin of the still more ancient crystalline schists. The first precipitated waters, according to him, acting on the anhydrous silicates of the earth's crust, at a very elevated temperature, and at a great pressure, which he estimated at two hundred and fifty atmospheres, formed a magma, from which, as it cooled, were successively deposited the various strata of the crystalline schists.[‡] This hypothesis, violating, as it does, all the notions which sound theory teaches with regard to the chemistry of a cooling globe, has, moreover, to encounter grave geognostical difficulties. The pre-Silurian crystalline rocks belong to two or more distinct systems of different ages, succeeding each other in discordant stratification. The whole history of these rocks, moreover, shows that their various alternating strata were deposited, not as precipitates from a seething solution, but under conditions of sedimentation very like those of more recent times. In the oldest known of them, the Laurentian system, great limestone formations are interstratified with gneisses, quartzites, and even with conglomerates. All analogy, moreover, leads us to conclude that even at this early period life existed at the surface of the planet. Great accumulations of iron-oxides, beds of metallic sulphids, and of graphite, exist in these oldest strata, and we know of no other agency than that of organic matter capable of generating these products.

Bischof had already arrived at the conclusion, which in the present state of our knowledge seems inevitable, that "all the carbon yet known to occur in a free state can only be regarded as a product of the decomposition of carbonic acid, and as derived from the vegetable kingdom." He further adds, "living plants decompose carbonic acid; dead organic matters decompose sulphates, so that, like carbon, sulphur appears to owe its existence in a free state to the organic kingdom."[§] As a decomposition (deoxidation) of sulphates is necessary to the production of metallic sulphids, the presence of the latter, not less than that of free sulphur and free carbon, depends on organic bodies; the part which these play in reducing and rendering soluble the peroxide of iron, and in the production of iron ores, is, moreover, well known. It was, therefore, that, after a careful study of these ancient rocks, I declared in May, 1858, that a great mass of evidence "points to the existence of organic life, even during the Laurentian or so-called azoic period."^{||}

This prediction was soon verified in the discovery of the Eozoön Canadense of Dawson, the organic character of which is now admitted by all zoologists and geologists of authority. But with this discovery appeared another fact, which afforded a signal verification of my theory as to the origin and mode of deposition of serpentine and pyroxene. The microscopic and chemical researches of Dawson and myself showed that the calcareous skeleton of this foraminiferous organism was filled with the one or the other of these silicates in such a manner as to make it evident that they had replaced the sarcose of the animal, precisely as glauconite and similar silicates have, from the Silurian times to the present, filled and injected more recent foraminiferous skeletons. I recalled, in connection with this discovery, the observations of Ehrenberg, Mantell, and Bailey, and the more recent ones of Forstskæ, to the effect that glauconite or some similar substance occasionally fills the spines of Echini, the cavities of corals and millepores, the canals in the shells of Balanus, and even forms casts of the holes made by burrowing sponges (Clonia) and

worms. The significance of these facts was further illustrated by showing that the so-called glauconites differ considerably in composition, some of them containing more or less alumina or magnesia, and one from the tertiary limestones near Paris being, according to Berthier, a true serpentine.*

These facts in the history of Eozoön were first made known by me in May 1864, in the *American Journal of Science*, and subsequently more in detail, February 1865, in a communication to the Geological Society of London.† They were speedily verified by Dr. Gumbel, who was then engaged in the study of the ancient crystalline schists of Bavaria, and who soon recognised the existence, in the limestones of the old Hercynian gneiss, of the characteristic Eozoön Canadense, injected with silicates in a manner precisely similar to that observed by Dawson and myself.‡ Later, in 1869, Robert Hoffmann described the results of a minute chemical examination of the Eozoön from Rapsenau, in Bohemia, confirming the previous observations in Canada and Bavaria. He showed that the calcareous shell of the Eozoön examined by him, had been injected by a peculiar silicate, which may be described as related in composition both to glauconite and to chlorite. The masses of Eozoön he found to be enclosed and wrapped around by thin alternating layers of a green magnesian silicate allied to picrosime, and a brown non-magnesian mineral, which proved to be a hydrous silicate of alumina, ferrous oxyd, and alkalies, related in composition to fahlunite, or more nearly to jollyte.§

Still more recently, in the course of the present year, Dr. Dawson detected a mineral insoluble in acids, injecting the pores of crinoidal stems and plates in a palæozoic limestone from New Brunswick, which is made up of organic remains. This silicate which, in decalcified specimens, shows in a beautiful manner the intimate structure of these ancient crinoids, I have found by analysis to be a hydrous silicate of alumina and ferrous oxyd, with magnesia and alkalies, closely related to fahlunite and to jollyte.|| The microscopic examinations of Dr. Dawson show that this silicate injected the pores of the crinoidal remains and some of the interstices of the associated shell-fragments, before the introduction of the calcite which cements the mass. I have since found a silicate almost identical with this, occurring under similar conditions in an Upper Silurian limestone said to be from Liangedoc in Wales.

Gumbel, meanwhile, in the essay on the Laurentian rocks of Bavaria, in 1866, already referred to, fully recognised the truth of the views which I had put forward, both with regard to the mineralogy of Eozoön and to the origin of the crystalline schists. His results are still further detailed in his *Gognost. Beschreibung der bayerischen Grenzgebirge*, 1868, p. 833. Credner, moreover, as he tells us,* had already from his mineralogical and lithological studies, been led to admit my views as to the original formation of serpentine, pyroxene, and similar silicates (which he cites from my paper of 1865, above referred to**), when he found that Gumbel had arrived at similar conclusions. The views of the latter, as cited by Credner from the work just referred to, are in substance as follows:—The crystalline schists, with their interstratified layers, have all the characters of altered sedimentary deposits, and from their mode of occurrence cannot be of igneous origin, nor the result of epigenic action. The originally formed sediments are conceived to have been amorphous, and under moderate heat and pressure to have arranged themselves, and crystallised, generating various mineral species in their midst by a change, which, to distinguish it from metamorphism by an epigenic process, Gumbel happily designates diagenesis.

It is unnecessary to remark that these views, the conclusions from the recent studies of Gumbel in Germany and Credner in North America, are identical with those put forth by me in 1860. At the early periods in which the materials of the ancient crystalline schists were accumulated, it cannot be doubted that the chemical processes which generated silicates were much more active than in more recent times. The heat of the earth's crust was probably then far greater than at present, while a high temperature prevailed at comparatively small depths, and thermal waters abounded. A denser atmosphere, charged with carbonic acid gas, must also have contributed to maintain, at the earth's

surface, a greater degree of heat, though one not incompatible with the existence of organic life.* These conditions must have favoured many chemical processes, which, in later times, have nearly ceased to operate. Hence we find that subsequently to the eozoic times, silicified rocks of clearly marked chemical origin are comparatively rare. In the mechanical sediments of later periods certain crystalline minerals may be developed by a process of molecular re-arrangement—diagenesis. These are, in the feldspathic and aluminous sediments, orthoclase, muscovite, garnet, staurolite, cyanite, and chialtolite, and in the more basic sediments, hornblende minerals. It is possible that these latter and similar silicates may sometimes be generated by reactions between silica on the one hand and carbonates and oxyds on the other, as already pointed out in some cases of local alteration. Such a case may apply to more or less hornblende gneisses, for example; but no sediments, not of direct chemical origin, are pure enough to have given rise to the great beds of serpentine, pyroxene, steatite, labradorite, &c., which abound in the ancient crystalline schists. Thus, while the materials for producing, by diagenesis, the aluminous silicates just mentioned, are to be met with in the mud and clay-rocks of all ages, the chemically formed silicates capable of crystallising into pyroxene, talc, serpentine, &c., have only been formed under special conditions.

The same reasoning which led me to maintain the theory of an original formation of the mineral silicates of the crystalline schists, induced me to question the received notion of the epigenic origin of gypsums and magnesian limestones or dolomites. The interstratification of dolomites and pure limestones, and the enclosure of pebbles of the latter in a paste of crystalline dolomite, are of themselves sufficient to show that in these cases, at least, dolomites have not been formed by the alteration of pure limestones. The first results of a very long series of experiments and inquiries into the history of gypsum were published by me in 1859, and further researches, reiterating and confirming my previous conclusions, appeared in 1866.† In these two papers it will, I think, be found that the following facts in the history of dolomite are established, viz.: first, its origin in nature by direct sedimentation, and not by the alteration of non-magnesian limestones; second, its artificial production by the direct union of carbonate of lime and hydrous carbonate of magnesia, at a gentle heat, in the presence of water. As to the sources of the hydrous magnesian carbonate, I have endeavoured to show that it is formed from the magnesian chlorid or sulphate of the sea or other saline waters in two ways:—first, by the action of the bicarbonate of soda found in many natural waters; this, after converting all soluble lime-salts into insoluble carbonate, forms a comparatively soluble bicarbonate of magnesia, from which a hydrous carbonate slowly separates; secondly, by the action of bicarbonate of lime in solution, which, with sulphate of magnesia, gives rise to gypsum; this first crystallises out, leaving behind a much more soluble bicarbonate of magnesia, which deposits the hydrous carbonate in its turn. In this way for the first time, in 1859, the origin of gypsums and their intimate relation with magnesian limestones were explained.

It was, moreover, shown that to the perfect operation of this reaction, an excess of carbonic acid in the solution, during the evaporation, was necessary to prevent the decomposing action of the hydrous mono-carbonate of magnesia upon the already formed gypsum. Having found that a prolonged exposure to the air, by permitting the loss of carbonic acid, partially interfered with the process, I was led to repeat the experiment in a confined atmosphere, charged with carbonic acid, but rendered drying by the presence of a layer of desiccated chlorid of calcium. As had been foreseen, the process under these conditions proceeded uninterruptedly, pure gypsum first crystallising out from the liquid, and subsequently the hydrous magnesian carbonate.‡ This experiment is instructive as showing the results which have attended this process in past ages, when the quantity of carbonic acid in the atmosphere greatly exceeded its present amount.

As regards the hypotheses put forward to explain the supposed dolomitisation of previously-formed limestones by an epigenic process, I may remark that I repeated very many times, under varying conditions, the often-cited experiment of Von Morlot, who claimed to have generated dolomite by the action of sulphate of magnesia on carbonate of lime, in the presence of water at a

somewhat elevated temperature under pressure. I showed that what he regarded as dolomite was not such, but an admixture of carbonate of lime with anhydrous and sparingly soluble carbonate of magnesia; the conditions in which the carbonate of magnesia is liberated in this reaction not being favourable to its union with the carbonate of lime to form the double salt which constitutes dolomite. The experiment of Marignac, who thought to form dolomite by substituting a solution of chlorid of magnesium for the sulphate, I found to yield similar results, the greater part of the magnesium carbonate produced passing at once into the insoluble condition, without combining with the excess of carbonate of lime present. The process for the production of the double carbonate described by Ch. Deville, namely, the action of vapours of anhydrous magnesium chlorid on heated carbonate of lime, in accordance with Von Buch's strange theory of dolomitisation, I have not thought necessary to submit to the test of experiment, since the conditions required are scarcely conceivable in nature. Multiplied geognostical observations show that the notion of the epigenic production of dolomite from limestone is untenable, although its resolution and deposition in veins, cavities, or pores in other rocks is a phenomenon of frequent occurrence.

The dolomites or magnesian limestones may be conveniently considered in two classes; first, those which are found with gypsums at various geological horizons; and secondly, the more abundant and widely distributed rocks of the same kind, which are not associated with deposits of gypsum. The production of the first class is dependent upon the decomposition of sulphate of magnesia by solutions of bicarbonate of lime, while those of the second class owe their origin to the decomposition of magnesian chlorid or sulphate by solutions of alkaline bicarbonates. In both cases, however, the bicarbonate of magnesia, which the carbonated waters generally contain, contributes a more or less important part to the generation of the magnesian sediments. The carbonated alkaline waters of deep-seated springs often contain, as is well known, besides the bicarbonates of soda, lime and magnesia, compounds of iron, manganese, and many of the rarer metals in solution, and thus the metalliferous character of many of the dolomites of the second class is explained. The simultaneous occurrence of alkaline silicates in such mineral waters, would give rise, as already pointed out, to the production of insoluble silicates of magnesia, and thus the frequent association of such silicates with dolomites and magnesian carbonates in the crystalline schists is explained, as marking portions of one continuous process. The formation of these mineral waters depends upon the decomposition of feldspathic rocks by subterranean or sub-aerial processes, which were doubtless more active in former ages than in our own. The subsequent action upon magnesian waters of these bicarbonated solutions, whether alkaline or not, is dependent upon climatic conditions, since, in a region where the rainfall is abundant, such waters would find their way down the river-courses to the open sea, where the excess of dissolved sulphate of lime would prevent the deposition of magnesian carbonate. It is in dry and desert regions, with limited lake-basins, that we must seek for the production of magnesian carbonates, and I have argued from these considerations that much of north-eastern America, including the present basins of the Upper Mississippi and St. Lawrence, must, during long intervals, in the palæozoic period, have had a climate of excessive dryness, and a surface marked by shallow enclosed basins, as is shown by the widely-spread magnesian limestones, and the existence of gypsum and rock-salt at more than one geological horizon within that area.* The occurrence of serpentine and diallage at Syracuse, New York, offers a curious example of the local development of crystalline magnesian silicates in Upper Silurian dolomitic strata under conditions which are imperfectly known, and which, in the present state of the locality, cannot be studied.†

Since the uncombined and hydrated magnesia mono-carbonate is at once decomposed by sulphate or chlorid of calcium, it follows that the whole of these lime-salts in a sea-basin must be converted into carbonates before the production of carbonated magnesian sediments can begin. The carbonate of lime formed by the action of carbonates of magnesia and soda, remains at first dissolved as bicarbonate, and is only separated in a solid form, when, in excess, or when required for the needs of living plants or animals, which are dependent for their supply of calcareous matter, on the bicarbonate of lime produced, in part by the process just described, and in part by the action of car-

bonic acid on insoluble lime-compounds of the earth's solid crust. So many limestones are made up of calcareous organic remains, that a notion exists among many writers on geology that all limestones are, in some way, of organic origin. At the bottom of this lies the idea of an analogy between the chemical relations of vegetable and animal life. As plants give rise to beds of coal, so animals are supposed to produce limestones. In fact, however, the synthetic process by which the growing plant, from the elements of water, carbonic acid and ammonia, generates hydrocarbonaceous and azotised matters, has no analogy with the assimilative process by which the growing animal appropriates alike these organic matters and the carbonate and phosphate of lime. Without the plant, the synthesis of the hydrocarbons would not take place, while independently of the existence of coral or mollusk, the carbonate of lime would still be generated by chemical reactions, and would accumulate in the waters until, these being saturated, its excess would be deposited as gypsum or rock-salt are deposited. Hence, in such waters, where, from any causes, life is excluded, accumulations of pure carbonate of lime may be formed. In 1861 I called attention to the white marbles of Vermont, which occur intercalated among impure and fossiliferous beds, as apparently examples of such a process.*

It is by a fallacy similar to that which prevails as to the organic origin of limestones, that Daubeny and Murchison were led to appeal to the absence of phosphates from certain old strata as evidence of the absence of organic life at the time of their accumulation.† Phosphates, like silica and iron-oxyl, were doubtless constituents of the primitive earth's crust, and the production of apatite crystals in granitic veins, or in crystalline schists, is a process as independent of life as the formation of crystals of quartz or of hematite. Growing plants, it is true, take up from the soil or the waters dissolved phosphates, which passed into the skeletons of animals, a process which has been active from very remote periods. I showed in 1854 that the shells of Lingula and Orbicula, both those from the base of the palæozoic rocks and those of the present time have (like Conularia and Serpulites) a chemical composition similar to the skeletons of vertebrate animals.‡ The relations of both carbonate and phosphate of lime to organised beings are similar to those of silica, which, like them, is held in watery solution, and by processes independent of life is deposited both in amorphous and crystalline forms, but in certain cases is appropriated by diatoms and sponges, and made to assume organised shapes. In a word, the assimilation of silica, like that of phosphate and carbonate of lime, is a purely secondary and accidental process, and where life is absent, all of these substances are deposited in mineral and inorganic forms.

I have thus endeavoured to sketch, in a concise and rapid manner, the history of the earlier rock-formations of eastern North America, and of our progress in the knowledge of them; while I have, at the same time, dwelt upon some of the geognostical and chemical questions which their study suggests. With the record of the last thirty years before them, American geologists have cause for congratulation that their investigations have been so fruitful in great results. They see, however, at the same time, how much yet remains to be done in the study of the Appalachians and of our north-eastern coast, before the history of these ancient rock-formations can be satisfactorily written. Meanwhile our adventurous students are directing their labours to the vast regions of western America, where the results which have already been obtained are of profound interest. The progress of these investigations will doubtless lead us to modify many of the views now accepted in science, and cannot fail greatly to enlarge the bound of geological knowledge.

THE SCOTTISH SCHOOL OF GEOLOGY §

II.

WHILE Hutton fortified his convictions by constant appeals to the rocks themselves, his disciple Hall tested their truth in the laboratory. It is the boast of Scotland to have led the way in the application of chemical and physical experiment to the elucidation of geological history. It was objected to Hutton's theory, that if basalt and similar rocks had ever been in a

melted state, they would now have been seen in the condition of glass or slag, and not with the granular or crystalline texture which they actually possess. Hall demolished this objection by melting basalt into a glass, and then by slow cooling reconvert-ing it into a granular substance like the original rock. Hutton had maintained that under enormous pressure, such as he conceived must exist under the ocean, or deep within the crust of the earth, even limestone itself might be melted without losing its carbonic acid. This was ridiculed by his opponents, on whom he retorted that they "judged of the great operations of the mineral kingdom from having kindled a fire and looked into the bottom of a little crucible." Hall, however, to whom fire and crucible were congenial implements, resolved to put the question to the test of experiment, and though, out of deference to his master, he delayed his task until after the death of the latter, he did at last succeed in converting lime-stone, under various great pressures, into a kind of marble, and even in reducing it to complete fusion, in which state it acted powerfully on other rocks. He concluded his elaborate essay on this subject with these words, "This single result affords, I conceive, a strong presumption in favour of the solution which Dr. Hutton has advanced of all the geological phenomena; for the truth of the most doubtful principle which he has assumed has thus been established by direct experiment."

Though they saw clearly the proofs which the rocks afford us of former revolutions, neither Hutton nor his friends had any conception of the existence of the great series of fossiliferous formations which has since been unfolded by the labours of later observers—that voluminous record in which the history of life upon this planet has been preserved. They spoke of "Alpine schistus," "primary" or "secondary" strata, as if the geological past had consisted but of two great ages—the second replete with traces of the destruction of the first. "The ruins of an older world," said Hutton, "are visible in the present structure of our planet." He knew nothing of the long, but then undiscovered, succession of such "ruins," each marking a wide interval of time. Nevertheless, for the establishment of the great truths which Hutton laboured to confirm, such knowledge was not necessary. On the other hand, it was most needful that the significance of that discordance between the older and newer strata which Hutton recognised should be persistently proclaimed. And the Huttonians, in spite of their limited range of knowledge and opportunity, saw its value and held by it.

2. But it was not merely, or even chiefly, for their exposition of the structure and history of the rocks under our feet that the geologists of the Scottish School deserve to be held in lasting remembrance. They could not, indeed, have advanced as far as they did in expounding former and ancient conditions of the planet, had they not, with singular clearness, perceived the order and system of change which is in progress over the surface of the globe at the present day. It was their teaching which first led men to see the harmony and co-operation of the forces of nature which work within the earth, with those which are seen and felt upon its surface. Hutton first caught the meaning of that constant circulation of water which, by means of evaporation, winds, clouds, rain, snow, brooks, and rivers, is kept up between land and sea. He saw that the surface of the dry land is everywhere being wasted and worn away. The scarped cliff, the rugged glen, the lowland valley, are each undergoing this process of destruction; wherever land rises above ocean, there, from mountain-top to sea-shore, degradation is continually going on. Here and there, indeed, the *débris* of the hills may be spread out upon the plains; here and there, too, dark angular peaks and crags rise as they rose centuries ago, and seem to defy the elements. But these are only apparent and not real exceptions to the universal law, that so long as a surface of land is exposed to the atmosphere it must suffer degradation and removal.

But Hutton saw, further, that this waste is not equally distributed over the whole face of the dry land, that while, owing to the greater or less resistance offered by different kinds of rocks, the rate of decay must vary indefinitely, the amount of material must necessarily be greatest where the surplus water flows off towards the sea, that is, along the channels of the streams. Water-courses, he argued, are precisely in the lines which water would naturally follow in running down the slope of the land from its water-shed to the sea, and which, when once selected by the surplus drainage, would necessarily be continually widened and deepened by the excavating power of the rivers. Hence he regarded the streams and rivers of a country as following the lines which they had chiselled for themselves out of the solid land, and thus he arrived at the deduction that valleys have been, inch by

inch and foot by foot, dug out of the solid framework of the land by the same natural agents—rain, frost, springs, rivers—by which they are still made wider and deeper. "The mountains," he said, "have been formed by the hollowing out of the valleys, and the valleys have been hollowed out by the attrition of hard materials coming from the mountains." This is a doctrine which is only now beginning to be adequately realised. Yet to Hutton it was so obvious as to convince him, to use his own memorable words, "that the great system upon the surface of this earth is that of valleys and rivers, and that however this system shall be interrupted and occasionally destroyed, it would necessarily be again formed in time while the earth continued above the level of the sea."

Although these views were again and again proclaimed by Hutton in the pages of his treatise, and though Playfair, catching up the spirit of his master, preached them with a force and eloquence which might almost have insured the triumph of any cause, they met with but scant acceptance. The men were before their time; and thus, while the world gradually acknowledged the teaching of the Scottish school as to the past history of the rocks, it lent an incredulous ear to that teaching when dealing with the present surface of the earth. Even some of the Huttonians themselves refused to follow their master when he sought to explain the existing inequalities of the land by the working of the same quiet unobtrusive forces which are still plying their daily tasks around us. But no incredulity or neglect can destroy the innate vitality of truth. And so now, after the lapse of fully two generations, the views of Hutton have in recent years been revived, and have become the war-cry of a yearly increasing crowd of earnest hard-working geologists.

While they insisted upon the manifest proofs of constant and universal decay over the surface of the globe, the Scottish geologists no less strongly contended that the decay was a necessary part of the present economy of Nature, that it had been in progress from the earliest periods in the history of the earth, and that it was essential for the presence of organised beings upon the planet. They pointed to the vegetable soil, derived from the decomposition of the rocks which it covers, and necessary for the support of vegetable life. They appealed to the vast quantity of sedimentary rocks forming the visible part of the crust of the earth, and bearing witness in every bed and layer to the degradation and removal of former continents. They showed that the accumulated *débris* of the land, carried to sea, was there spread out on the sea-floor to form new strata, which, in due time hardened into solid rock, would hereafter be upheaved to form the framework of new lands.

Such was the geology of the Scottish School. It was based not on mere speculation, but on facts drawn from mountain and valley, hill and plain, and tested as far as was then possible by the scrutiny of actual experiment. It strove, for the first time in the history of science, to evolve a system out of the manifold complications of nature, to harmonise what had seemed but the wild random working of subterranean forces with the quiet operations in progress upon the surface of the earth, to understand what is the present system of the world, and through that to peer into the history of the earlier conditions of the planet. It taught that the earthquake and volcano were parts of the orderly arrangement by which new continents were from time to time raised up to supply the place of others which had been worn away; that the surface of the land required to decay to furnish life to plants and animals; that in the removal of the *débris* thus produced mountains and valleys were carved out; and that in the depths of the ocean there were at the same time laid down the materials for the formation of other lands, which in after ages would be upheaved by underground forces, to be anew worn away as before. The Scottish School proclaimed that in the inorganic world there is ceaseless change, that this change is the central idea of the system, and that in its constant progress lie the conditions necessary for the continuance of our earth as a habitable globe.

That Hutton and his followers should have seen only a part of the truth, that they did not perceive the full scope which their views would ultimately acquire, that they fell into errors, and attached to some secondary parts of their system an importance which we now see to have been misplaced, is only what may be said of any body or men who, at any time, have led the way in a new development of human inquiry. But, after all allowance is made for such shortcomings, we see that their errors were for the most part on mere matters of detail, and that: he fundamental principles which they laboured to establish have become the very life and soul of modern geology

I have spoken of this Scottish School as marking a period of activity which rose into brightness and then waned. It is only too true, that so far as the originality and influence of its cultivators go, Geology has never since held in Scotland the place which it held here at the beginning of the century. Its decay is perhaps to be ascribed chiefly, if not entirely, to the introduction of the doctrines of Werner from Germany. The Huttonians had dealt rather with general principles than with minute details; they were weak in accurate mineralogical knowledge—not that they were ignorant of or in any degree despised such knowledge; but it was not necessary for their object. When, however, the system of Werner came to be taught within these walls by his enthusiastic pupil Jameson, its precision and simplicity, and its supposed capability of ready application in every country, joined to the skill and zeal of its teacher, gave it an impulse which lasted for years. I shall have occasion in a subsequent lecture to speak of this system. It is enough for the present to describe it as a crude and artificial attempt to explain the geological history of the globe from the rocks of a district in Saxony. It required mineralogical determination of rocks, and in so far it did good service, but its theoretical teaching in matters of geology cannot now be regarded without a smile. It maintained that the globe was covered with certain universal formations, and that these had been precipitated successively from solution in a primeval ocean. Of upheaval and subsidence, earthquakes and volcanos, and all the mechanism of internal heat, it could make nothing, and ignored as much as it dared. Werner, the founder of this system, had the faculty of attaching his students to him, and of infusing into them no small share of his own zeal and faith in his doctrines. His pupil Jameson had a similar aptitude. Skilled in the mineralogy of his time, and full of desire to apply the teachings of Freyberg to the explication of Scottish geology or *geognosy*, as he preferred to call it, he gathered round him a band of active observers, who gleaned facts from all parts of Scotland, and to whom the first accurate descriptions of the mineralogy of the country are due. It is but fitting that a tribute of gratitude should on the present occasion be offered to the memory of Jameson for the life-long devotion with which he taught Natural History, and especially Mineralogy, in this University. His influence is to be judged not by what he wrote, but by the effect of his example, and by the number of ardent naturalists who came from his teaching. He founded a scientific Society here, and called it *Wernerian*, after his chief—a Society which under his guidance did excellent service to the cause of science in Scotland. And yet in the course of my scientific reading I have never met a sadder contrast than to turn from the earlier volumes of the Royal Society of Edinburgh, containing the classic essays of Hutton, Hall, and Playfair—essays which made an epoch in the history of Geology—to the pages of the *Wernerian* memoirs, and find grave discussions about the universal formations, the aqueous origin of basalt, and the chemical deposition of such rocks as slate and conglomerate!

Between the followers of Hutton and Werner there necessarily arose a keen warfare. The one battalion of combatants was styled by its opponents "Vulcanists" or "Plutonists," as if they recognised only the power of internal fire, while the other was in turn nicknamed "Neptunists," in token of their adherence to water. The warfare lasted in a desultory way for many years, and though the *Wernerian* school, having essentially no vitality, eventually died out, and its leader Jameson publicly and frankly recanted his errors, the early Huttonian magnates had one by one departed and left no successors. The Huttonian school triumphed indeed, but its triumph was seen rather in other countries than in Scotland. Here the *Wernerian* school attracted in great measure the younger men who gathered round Jameson, and when its influence waned there were no great names on the other side to rally the thinned and weakened ranks of Huttonianism. Hence came a period of comparative quiescence, which has lasted almost down to our own day. From time to time, indeed, a geologist has arisen among us to show that the science was not dead, and that the doctrines of Hutton had borne good fruit. But Geology has never since held such a prominent place amongst us, nor have the writings of geologists in Scotland taken the same position in the literature of the science. The great name of Lyell, and others of lesser note, have earned elsewhere their title to fame.

But there is one name which must be in our hearts and on our lips to-day, that of Roderick Impey Murchison. To his munificence, and the liberality of the Crown, we owe the foundation of this Chair of Geology, and to his warm friendship I am indebted for the position in which I stand before you. Of his

achievements in science, and of the influence of his work all over the world, it is not necessary now to speak. But on Scottish Geology no man has left his name more deeply engraven. It was he who, along with Prof. Sedgwick, first made known the order of succession of the Old Red sandstone of the north of Scotland; it was he who sketched for us the relations of the great Silurian masses of the Southern uplands; and it was he who, by a series of admirable researches, brought order out of the chaos of the so-called Primary rocks of the Highlands, and placed these rocks in a parallel with the Silurian strata of other countries. These labours will come again before us in detail, and you will then better understand their value, and the debt we owe to the man who accomplished them.

Sir Roderick Murchison looked forward with interest to the occasion which has called us together to-day. Only a few weeks ago I talked with him regarding it, and his eye brightened as I told him of the subject on which I proposed to speak to you. I had hoped that he would have lived to see this day, and to hear at least of the beginning of the work which he has inaugurated for us in this University. But this was not to be. He has been taken from us ripe in years, in work, and in honours, and he leaves us the example of his unwearied industry, his admirable powers of observation, and his rare goodness of heart.

In the course of study now before us, we are to be engaged in examining together the structure and history of the earth. We shall trace the working of the various natural agents which are now carrying on geological change, and by which the past changes of the globe have been effected. In so doing we shall be brought continually face to face with the history of life as recorded in the rocks—for it is by that history mainly that the sequences of geological time can be established. We shall thus have to trespass a little on what is the proper domain of the professors of botany and of natural history. But you will find that no hard line can be drawn between the sciences. Each must needs overlap upon the other; and indeed it is in this mutual interlacing that one great element of the strength and interest of science lies. From Profs. Balfour and Wyville Thomson you will learn the structure and the relation borne to living plants and animals by the fossils with which we shall have to deal as our geological alphabet. By Prof. Crum Brown you are taught the full meaning and application of the chemical laws under which the minerals and rocks, which we in this class must study, have been formed, and of the processes concerned in those subsequent changes, both of rocks and minerals, which are of such paramount importance in Geology.

And now, in conclusion, permit me to give expression to the feelings which must strongly possess the mind of one who is called upon to fill the first Chair dedicated in Scotland to the cultivation of Geology. When I look back to the times of that illustrious group of men—Hutton, Hall, Playfair—who made Edinburgh the special home of Geology; of Boué and Macculloch, who gave to Scottish rocks and mountains an European celebrity; of Jameson and Edward Forbes, who did so much to stimulate the study of Geology and Mineralogy in this University; and to the memory of Hugh Miller and Charles Maclaren, who fostered the love of the sciences throughout the community here, and to whose kindly friendship and guidance, given to me in my boyhood, I would fain express my hearty gratitude—when I cast my thoughts back upon these recollections, it would be affectation to conceal the anxiety with which the prospect fills me. The memory of these great names arises continually before me, bearing with it a consciousness of the responsibility under which I lie to labour earnestly not to be unworthy of the traditions of the past. And, gentlemen, I feel deeply my responsibility to you who are to enter with me upon a yet untrodden path of the Academic curriculum. It is only experience that will show us how we shall best travel over the wide field before us. In the meantime I must bespeak your kindly forbearance. While I shall cheerfully teach you all I know, and confess what I do not know, I would fain have you in the end to regard me rather in the light of a fellow-student, searching with you after truth, than of a teacher putting before you what is already known. We have now an opportunity of combined and sedulous work which has not hitherto been obtainable in Scotland. We may not rival a Hutton or a Hall; but we may at least try to raise again the standard of geological inquiry here. On every side of us are incentives to study. Crag and hill rise around us, each eloquent of ancient revolutions, and each a silent witness of the revolution in progress now. At our very gates tower on one side the picturesque memorials of long silent volcanoes, with their crumbling lavas and ashes. On the other lie the buried vegetation of an

ancient land, and the corals and shells of a former ocean. Everywhere the scarred and wasted rocks tell of the degradation of the solid land, and show us how the waste goes on. Let us then carry into our task some share of the enthusiasm which these daily exemplars called forth in earlier days. Let us turn from the lessons of the lecture room to the lessons of the crags and ravines, appealing constantly to Nature for the explanation and verification of what is taught. And thus, whatsoever may be your career in future, you will in the meantime cultivate habits of observation and communion with the free fresh world around you—habits which will give a zest to every journey, which will enable you to add to the sum of human knowledge, and which will assuredly make you wiser and better men.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, November 7.—Prof. Newton, F.R.S., vice-president, in the chair. The secretary read a report on the additions that had been made to the society's menagerie during the months of June, July, August, and September 1871, amongst which were specimens of the Tamandua Ant-eater (*Tamandua tetradactyla*), Baird's Tapir (*Tapirus bairdi*), and several other animals of special interest.—A communication was read from Mr. Gerard Krefft, Curator of the Australian Museum, Sydney, N.S.W., containing notes on a rare Ziphioid Whale, which had been stranded near Sydney, and which appeared to be referable to *Ziphius cavirostris*.—Mr. Gould exhibited and characterised a small but lovely Fruit Pigeon from the Fiji Islands, which he proposed to name *Chrysena victor*.—Mr. Slater called attention to the supposed existence of an undescribed animal, of about the size of a Dingo, in the Rockingham Bay district of Queensland, and read a letter addressed to him by Mr. Brinsley G. Sheridan, containing particulars on this subject.—Dr. John Anderson, of Calcutta, communicated a description of a short tailed Macaque from Upper Burma, supposed to be new, which he proposed to call *Macacus brunneus*.—A communication was read from the Viscount Walden on a new and interesting Falconine Bird, of the genus *Polyborus*, recently obtained by Major Lloyd, in the vicinity of Tongoo, Upper Burma, and proposed to be called *Polyborus insignis*.—Mr. W. H. Flower, F.R.S., read a memoir on the recent Ziphioid Whales, among which he proposed to recognise the following generic types:—*Hydroodon*, *Ziphius*, *Neopodopod*, and *Beardius*. This was followed by a description of the skeleton of *Beardius arnouxii*, founded on a specimen lately transmitted to the Museum of the Royal College of Surgeons from New Zealand by Dr. J. Haast, F.R.S.—Mr. Herbert Viper Usher read some notes on the habits of the Horned Viper (*Vipera nasicornis*), as observed by him in the vicinity of Cape Coast Castle, Western Africa.—Prof. Newton read a notice of a remarkable peculiarity which he had recently discovered in an Australian duck, *Anas punctata*, viz., that in this species the osseous development of the lower trachea was common to both sexes.—A paper by Dr. J. C. Cox, of Sydney, was read, describing a new Volute and twelve new species of Land Shells from Australia and the Solomon Islands.—A communication was read from Surgeon Francis Day, Inspector-General of Fisheries of British India, containing some remarks on the identification of certain species of Indian Fishes.—Mr. P. L. Slater, F.R.S., read some notes on Pelicans, being supplementary to a previous paper on the same subject read at a meeting of the society in May, 1868.—A communication was read from Mr. J. Brazier, of Sydney, containing descriptions of eight new Australian Land Shells.—Prof. Newton communicated a paper by Dr. J. Murie, containing supplementary notes concerning the powder-down patches of *Rhinoceros jubatus*.

Anthropological Institute, November 6.—Sir John Lubbock, Bart., F.R.S., president, in the chair. Mr. M. Allport, F.R.S., was selected a corresponding member for Tasmania.—Mr. J. W. Flower, F.G.S., treasurer, read a paper "On the relative ages of the Flint and Stone Implement Periods in England." In this paper, which was illustrated by the exhibition of a series of various kinds of flint implements, the author proposed to show, that having regard to recent discoveries, the arrangement hitherto adopted regarding the Prehistoric Stone period in England as divisible into the Palæolithic and Neolithic was altogether inadequate, and that as well on Geological as on Palæontological grounds the drift period was separable by a vast interval from that of the bone Caves, as the cave period was separable from

the Tumulus or Barrow period. The author adduced various reasons for believing that the implements were made and the drift gravel was thrown down long before this island was severed from the Continent, and that thus before that event both countries were inhabited. He also contended, on this and other grounds founded upon recent discoveries, that the implements could not have been transported (if transported at all by fluvial action) to the places in which they are found by any rivers flowing in the same channels and draining the same areas as now; and he also expressed doubts whether the gravels were transported by river action, and also whether the makers of the implements were contemporary with the Mammalia with whose remains they were associated; the gravel and the fossils having been evidently carried from considerable distances, whereas the implements were made on the spot from stones taken from the gravel. Mr. Flower then pointed out that the works of art found in the caves, as well as the animal remains, differed in many important particulars from those found in the drift, and that those of the Tumulus period differed entirely from those in the caves; that in truth the cave fauna had then quite disappeared, and had been succeeded by one entirely different, including most of our domestic animals, and that for effecting such a change an interval of long duration must be allowed. He also pointed out that the use of bronze was common to both what were known as the Palæolithic and Neolithic periods, and could not be regarded therefore as it usually has been, as distinct from and posterior to both; and, in conclusion, he suggested that the drift period might properly be termed Palæolithic, that of the caves as Archaic, that of the Tumuli as Prehistoric, whilst that of the polished stones might still be known as Neolithic.

Geologists' Association, November 3.—The Rev. Thomas Wiltshire, M.A., F.G.S., president, in the chair. "On the old Land Surfaces of the Globe," by Prof. Morris, F.G.S. The indications of land surfaces to be found in Palæozoic, Mesozoic, and Cainozoic strata were recapitulated. Conglomerates and ripple marks, as well as the great thickness of the oldest sedimentary rocks, the result of denudation, clearly show the existence of land during Cambrian and Silurian times. Though there are indications of vegetable life in Cambrian rocks, the earliest remains of vegetable organisms allied to our present land plants occur in the uppermost Silurian Strata, or passage beds. The Old Red sandstone of Scotland affords evidence of fresh-water origin, and consequently of lakes and land. But in carboniferous rocks we have in the vast accumulations of vegetable remains forming the great coal beds of the world, perhaps the most striking and conclusive proof of land and terrestrial conditions to be found in the geologic record. After noticing the indications of land in the Permian rocks, the Mesozoic reptilia and mammalia, as well as the many other evidences of land surfaces to be met with in the Secondary rocks, were dwelt upon; and a similar review of Cainozoic, or Tertiary, terrestrial indications was followed by an exposition of the upward and onward progress of life, culminating in the present conditions of the globe with a flora and a fauna admirably adapted to the wants of the latest addition to the marvels of the universe, man, whose duty it is, and whose pleasure it ought to be, to study those successive changes, the grand result of which he now enjoys.—A note "On recent exposure of the Glacial Drift at Finchley" was read by Mr. H. Walker. This was a brief notice, and intended as an introduction of the subject, which will be more fully elucidated in a paper by the same author to be read at the next meeting of the association.

Society of Biblical Archæology, November 7.—Dr. S. Birch, president, in the chair. Dr. Richard Cull, F.S.A., read a paper contributed by Mr. Henry Fox Talbot, F.R.S., "On the Religious Beliefs of the Assyrians."—Mr. K. Hamilton Lang, H.B.M. Consul at Cyprus, read a paper "On the Discovery of some Cypriote Inscriptions." After stating that the credit was due to Duc de Luynes of having proved the existence of a Cypriote alphabet, he enumerated the various inscriptions which he had himself discovered, and drew especial attention to one, a bi-lingual inscription in Phœnician and Cypriote, which he first discovered during the excavation of a temple at Idalion. The alphabet, which had been compiled by the Duc de Luynes, consisted of 80 letters, but Mr. Lang felt justified in reducing that number to 51, and exhibited an alphabet which he believed to contain all the Cypriote characters of which we are at present certain. In proceeding he dwelt at some length upon an apparent resemblance between

the Cypriote and Lycian alphabets, and stated that they were both derived from the same source, the Lycians having however engrafted upon the ancient forms a great many Grecian Letters, while in Cyprus the character was preserved in its original fullness and power. Mr. Daniel Sharpe had endeavoured to prove that the Lycian alphabet was of Indo-Germanic origin, and so also might be the Cyprian. Mr. Lang alluded to the attempt which had been made both by De Luyne and von Röh to read the Cypriote writing, especially as regarded a word which both gentlemen agreed in rendering "Salamis," and which they considered to be the key to the Cypriote characters. Mr. Lang, on the contrary, gave his reasons for dissenting from this reading upon the testimony of coins, and showed why he thought that the word should be read as "King." The evidence of the bi-lingual inscription before referred to was dwelt upon in confirmation of this reading. A resemblance was further pointed out between the word translated "king" by Mr. Sharpe in Lycian, and that proposed to be read in the same way in Cypriote, and a reading was suggested for the whole of the first line in the Cypriote part of the bi-lingual inscription. Many other points of interest connected with this alphabet were also detailed, and Mr. Lang concluded by observing that in it "we have a child long lost both to the sight and knowledge of the world, and he felt convinced that more extended research would prove that the pedigree of the founding was of more than usual philological interest and importance."—Mr. G. Smith then read a paper "On the Decipherment of the Cypriote Inscriptions," in which, after alluding to the antiquities discovered by General Cesnola and Mr. Lang, particularly the bi-lingual inscription already mentioned, he went on to detail the discovery of the values of eighteen Cypriote signs from that inscription alone. He further related the discovery of the sounds of twenty other signs by comparison of various texts, together with the reading of the names "Idalion Citium Evagoras," and many others. His conclusions were that the Cypriote language belonged to the Aryan group, and was written with about fifty-four syllabic signs. Diagrams showing case endings of nouns, proper names, and part of the bi-lingual inscription, illustrated the paper. A collection of electrotypes of the Cypriote coins referred to in the foregoing papers was exhibited by Mr. Ready of the British Museum.

PARIS

Academy of Sciences, November 6.—A memoir was read by M. A. Mannheim on the properties relating to the infinitely small displacements of a body when these displacements are only defined by four conditions, and one by M. Maurice Lévy on the integration of equations with partial differences relating to the internal movements of ductile solid bodies, when these movements take place in parallel planes.—M. Phillips also communicated a memoir containing a summary of observations made during the last seven years at the Observatory of Neuchâtel upon chronometers furnished with spirals with theoretical final curves.—M. P. A. Favre presented a continuation of his thermic investigations upon electrolysis. This paper contains chiefly the results of experiments upon various acids.—General Morin communicated a paper by M. H. Tresca on the effects of torsion prolonged beyond the limits of elasticity.—M. Le Verrier communicated a note on the observation of the flight of meteors of the 12th, 13th, and 14th of this month at the stations of the French Scientific Association.—M. E. Peligot presented a further memoir on the distribution of potash and soda in plants, upon which MM. Dumas and Chevreul made some remarks.—M. I. Pierre presented some observations on the solubility of chloride of silver, with reference to the note on this subject recently communicated by M. Stas.—M. Peligot communicated a note by M. J. Bouis on the determination of hydrochloric acid in cases of poisoning, in which he recommends the heating of the filtered liquids in contact with a plate of gold at the addition of a few fragments of chlorate of potash. The dissolution of the gold indicates the presence of hydrochloric acid, and it is determined by means of protochloride of tin.—M. Berthelot presented a note on the formation of precipitates, in which he commenced the discussion of the phenomena connected therewith, and noticed especially the heat evolved or absorbed during the formation of a solid compound, and the dehydration of precipitated compounds.—A note by M. F. Cayrol on the Lower Cretaceous formation of Corbières was presented by M. Milne-Edwards. The author compared this formation with that of the Clape, formerly described by him, and stated that it consisted in ascending order of a marly clay containing *Orbitolina*, a thick limestone with *Requienia Lonsdattii*, and a second *Orbitolina*-zone, the latter overlain by the Gault.—A note by M. Guido

Susain was also read on an improved method of managing the egg-laying of the silkworm moth.—The tables of meteorological observations made at Paris in October was communicated to the Academy.

SCIENCE FOR WOMEN

IN the present condition of the two questions of Science Teaching and of the Higher Education of Women, it may be worth while to regard them for a moment from that point of view in which they coalesce, to inquire, in other words, what is being done for the scientific instruction of women. We do not propose now to argue the question whether it is desirable that women should learn science—that we take to be already decided; but rather to speak of the extent to which, at the present time, provision is being made for carrying out this object. The attention of the public was called to the subject a fortnight ago by the publication of the report of the Syndicate appointed by the University of Cambridge for the examination of women above eighteen years of age in July last. The following are the portions of this report which refer to the various subjects coming within our scope:—

“The answers in the present year in Mathematics show a marked improvement upon those in 1870. The Euclid was decidedly well done, one candidate answering every question except one rider. The conic sections were tried by only two, and without any great success, nothing being attempted in analytical geometry. The algebra was creditably done, but I observe, as I did last year, that while the candidates are fairly skilled in the management of symbols, they seem to have little idea of a logical proof. I should recommend, in this subject, a much more careful study of proofs of rules. The trigonometry, making allowance for the greater intrinsic difficulty of the subject, was better done than the algebra. Statics, astronomy, and dynamics were taken by very few candidates, one of whom, however, showed a knowledge of these subjects small in amount, but thoroughly sound as far as it went. It may be worth while to remark that one candidate, who took in Euclid and algebra only, was the best in each of these subjects.

“In Botany and Zoology the examiner states that the number of candidates was so small as to give little scope for a report. The examination was satisfactory, as far as was possible under the circumstances. One of the candidates passed with distinction. In Geology and Physical Geography the examiner reports as follows:—‘No one has done well. The answers are in most cases shallow and full of bad blunders. The examinees seem not to have sufficient acquaintance with the simple laws of physics to make much progress; for instance, it was plain that some did not understand the ordinary laws of evaporation and condensation of vapour, and it seems to me impossible to understand the causes of clouds and rainfall without such preliminary knowledge. There seemed no better foundation laid in geology. More than one confounded Plutonic with Laurentian rocks. No one showed a tolerable acquaintance with the outlines of systematic geology, or any knowledge at all of Palæontology.’”

The report, though in some respects not unsatisfactory, shows how very much still remains to be done before even a fair start can be said to be made in a general training of our women in the elements of Natural and Physical Science. It is therefore with great pleasure that we welcome the attempts, unconnected and imperfect though some of them may be, which are now being made to remedy this defect.

To place the matter on its right footing, it is essential that the work should be undertaken by the very best teachers we have at our command; and in London at least this is being done in a manner that must in time bring forth good fruit. The classes for women conducted last season at South Kensington by Professors Huxley, Guthrie, and Oliver were attended by large and highly appreciative audiences; and the programme for the present season, already announced by Professors Duncan, Guthrie, and Huxley, is no less attractive. The Ladies' Educational Association of London has wisely confined its teaching to that of the professors of University College, thus affording a guarantee that the instruction shall be of a first-class kind; and now that the whole scientific staff of the College has placed its services at the disposal of the Association, and the Council has given permission for the lectures to be delivered within its walls, with full use of its philosophical apparatus, a scientific training is for the first time offered to ladies on a par with that obtained by its male students. We learn that the classes named in the programme have all been started, and with a fair number of entries. That there is great room for instruction of this kind is shown also by the eagerness with which women take advantage of the opportunity of attending mixed classes wherever they are conducted by men of high repute. We need only refer to the success which has attended Prof. Huxley's lectures at the London Institution in Finsbury Circus, especially as regards the position taken by girls at the examinations in previous years, and to the crowded audiences, consisting at least half of ladies, who are now attending his course on Elementary Physiology.

In the provinces the same work is going on, though hardly with the same degree of organisation. The professors of the University of Cambridge in particular have shown a praiseworthy zeal in the cause, and have offered their time and their services for a more general system of instruction than could be comprised within the lectures which have been given during the last two years at Cambridge itself. We referred last week to the attempt now being made at the College for Women at Hitchin—to be removed, whenever sufficient funds can be obtained, to Cambridge—to inaugurate systematic instruction in Chemistry as an introduction to the other sciences, an attempt to which we heartily wish the success it deserves. When the College for Physical Science was founded at Newcastle, the Council took into consideration a request from a number of ladies of the neighbourhood that women should be admitted to its classes, and decided to make no restriction as to sex in the admission of students or in the rules to which they should be subject. Greatly, however, to the disappointment of the Professors themselves, after all this preparation, when the time came not a single lady presented herself as a pupil. We cannot but think that the ladies of Newcastle were ill-advised in urging the subject upon the Council when there was no actual demand among them for the instruction itself, and thereby giving occasion for unjust reflections on the genuineness of the desire among women for instruction in science.

We wish we could refer with the same satisfaction to the present position of the question in Scotland. The ladies of Edinburgh have shown their high appreciation of the opportunity that has been offered them by several

of the Professors of the University for the highest intellectual training, and the Ladies' Educational Association of the Scottish capital has been among the most successful in the kingdom. Emboldened probably by the favour with which the cause of female education was received in Edinburgh, several ladies applied to the University for instruction in a purely medical course of studies; and, the required permission having been obtained, pursued with credit and success the earlier portion of their studies. When they had advanced thus far, however, an unexpected obstacle arose, and the highest governing body of the University, the Senate, stepped in and barred all further progress. The mode, indeed, in which the authorities of the University have played fast and loose with the question of the medical education of women redounds little to their credit. It remains to be seen whether the Council will consent, at the bidding of the Senate, to rescind the regulations which they themselves freely passed in 1869, with the sanction of the Senate, viz. :—

“Women shall be admitted to the study of medicine in the University. The instruction of women for the profession of medicine shall be conducted in separate classes, confined entirely to women. The professors of the Faculty of Medicine shall, for this purpose, be permitted to have separate classes for women. All women attending such classes shall be subject to all the regulations now or at any future time in force in the University as to the matriculation of students, their attendance on classes, examination, or otherwise.”

Any proposal for mixed classes of both sexes in purely medical subjects excites so great a repugnance both among the teachers and students of medicine that it would be extremely unwise to press it; but it will be observed that no such question has been raised here, and no such request has ever been made by the lady medical students. The best of the medical as well as the general press of London has been almost unanimous in pointing out the undignified position in which the Senate now stands; and it is earnestly to be hoped that wiser counsels will prevail, and that the University will in future pursue a course which will give greater satisfaction to all its best friends.

We noticed with pleasure the large and comprehensive views expressed by Lord Lyttelton when presiding last week over a meeting of the National Union for Improving the Education of Women of all Classes. Lord Lyttelton's position as Chairman of the Endowed Schools' Commission rendered peculiarly important the opinion he expressed as to the misappropriation of the enormous educational endowments of the country to the benefit of male students only.

The extreme importance to all women, as great if not greater than to men, of an acquaintance with the elements of human physiology and of the laws which govern the body in health and sickness, was admirably set forth in an introductory lecture by Prof. Bennett to his ladies' class at Edinburgh, a portion of which will be found in our present number. The advantage which the community, no less than individuals, will gain when some knowledge of Natural and Physical Science is spread throughout our female population, is so obvious that we have no fear but that the movement now happily inaugurated will spread and prosper in spite of temporary checks and disappointments.

ALLEN'S MAMMALS OF FLORIDA

On the Mammals and Winter Birds of East Florida: with an Examination of Certain Assumed Specific Characters in Bird Fauna of Eastern North America.
By J. A. Allen, Cambridge, U.S.A. 1871.

THIS essay forms a portion of the second volume of the “Bulletin of the Museum of Comparative Zoology at Harvard College, Cambridge, Mass.,” in which work Prof. Agassiz and his disciples are giving to the world the results arrived at from the study of the rich collections accumulated during the past few years under their charge. Its author is almost new to the particular branch of zoology which he now enters upon, and puts forward his views in a very decided and uncompromising manner. Yet he has obviously taken great pains in the investigations which have conducted to his results, and has, it must be allowed, to a certain extent, proved his point, although, as is usual with most reformers, he has in some cases pushed his theories too far.

Mr. Allen's paper embraces, as he tells us in his Introduction, “five more or less distinct parts.” The first contains remarks on the topography, climate, and fauna of Florida, based principally upon observations made during a three months' expedition to that country in the winter of 1868-9. The second portion contains an annotated list of the Mammals of Eastern Florida. In this list some unusual identifications are made—e.g., the Common American Fox (*Canis fulvus*, auct.) is identified with *Canis vulpes* of Europe, and the American Black Bear (*Ursus americanus*) is considered inseparable from *Ursus arctos*. In Part III. we have the reasons which have led the author to adopt these and similar views as to certain species in the class of birds hitherto considered to be distinct put forward at considerable length. The examination of the extensive series of the common North American Birds in the Museum of Comparative Zoology “has disclosed a hitherto unsuspected range of purely individual differentiation in every species thus far studied. . . . Local or geographical variations have been likewise carefully considered, with results that were a short time since unsuspected. . . . These several lines of investigation have shown that in many instances what have been regarded as reliable characteristics of species, have in not a few cases little or no value, that the importance of many diagnostic features has been too highly estimated, and that consequently a careful revision of our published fauna will be necessary for the elimination of the merely nominal species.” To all this every true naturalist will give his cordial assent. We are all for reform and revision, when founded on sufficient evidence. But on turning to Part IV. of our author's work, it would appear that some of his identifications have been based on mere conjecture without any evidence at all. For example: *Quiscalus brachypterus* of Porto Rica and *Q. crassirostris* of Jamaica are placed as synonyms of *Q. purpureus*. Yet it does not appear, or at all events is not stated, that the author has ever examined authentic specimens of the two former species. Again, *Chordeiles texensis* is united to *C. popetue* without any further remark than that “this widely distributed species presents the usual variations in size and colour.” Such and similar errors will, we fear, tend to discredit the identifications which Mr. Allen has

discreetly made between certain supposed species, of which he has examined a large series of specimens in a most exhaustive and painstaking manner.

In Part V. of his memoir Mr. Allen treats of the geographical distribution of the birds of North America, "with special reference to the number and circumscription of the ornithological faunæ." In this essay, which well merits perusal, although it is evident that the author has never made himself acquainted with some of the most certainly ascertained facts of the general distribution of bird-life,* a new and arbitrary division of the world's surface into eight "realms" is proposed.

The division of North America, however, into its constituent sub-faunæ is fully discussed and well worked out. An appendix to the volume contains a list of authorities to be consulted on the geographical distribution of North American birds, which will be useful, although by no means well arranged. Mr. Allen's knowledge of the geography of Central America seems, moreover, to be somewhat imperfect, as Mr. Salvin's articles on the birds of Veragua are placed under "Guatemala," and papers relating to British Honduras (*i.e.*, Belize), the Republic of Honduras, and Nicaragua, are all confounded under one head. P. L. S.

OUR BOOK SHELF

Sir Isaac Newton's Principia. Reprinted for Sir W. Thomson, LL.D., and Hugh Blackburn, M.A. (Glasgow: Maclehose.)

FINDING that all editions of the *Principia* are out of print, the Glasgow Professors of Natural Philosophy and of Mathematics have issued a careful reprint of the last (third) edition as finally revised by Newton himself; attending, of course, to the *Corrigenda*, but wisely abstaining from the insertion of either note or comment. We have had far too much of such things. Think only of the painfully elaborate notes of poor Bishop Horsley, which deface an otherwise splendid edition, and of the truly amazing comments made by Lord Brougham in his "Analytical Views!" True, these are coarse attempts at painting, or rather at "whitewashing," while the Glasgow professors are quite able to "gild." But even gilding would have had a smack of profanation about it, and we are delighted to have Newton left to speak for himself in the old, imperishable, words whose full meaning is only now gradually dawning on the world. So far as we have compared it with other copies, this edition seems to be better than any of its predecessors; the printing and paper are excellent, and the cuts especially are greatly improved. There is, however, one remark which is forcibly thrust upon us by this performance. How eccentric and inscrutable are mathematicians! Comets are nothing to them; and the greater they are, the less do they seem subject to any law of what would be called common sense by mere average humanity. One man of exceptional genius is found wasting day after day in neatly rounding off a sonnet; anon he calculates, to fifty places more than can ever be required, the root of some transcendental equation. Others occasionally burst from their seclusion and rush wildly into gymnastic feats, high-jinks, and what not; but in cold blood to determine to verify, letter by letter, a reprint of a somewhat bulky Latin book seems a species of self-torture, of which nothing we ever before heard concerning our northern friends, could have led us

to imagine them capable. They have gone through it, however; and, having done it well, deserve our hearty thanks.

Description of an Electrical Telegraph. By Sir Francis Ronalds, F.R.S. (London: Williams and Norgate.)

SIR FRANCIS RONALDS has done well in republishing this portion of his work, which was first printed in 1823. The hope which he expresses in the preface to this reprint that his name "may remain connected with an invention which has conferred incalculable benefits on mankind," is quite justified by the experiments which he made and published many years before the final success of telegraphy. Sir Francis, before 1823, sent intelligible messages through more than eight miles of wire insulated and suspended in the air. His elementary signal was the divergence of the pith balls of a Canton's electrometer produced by the communication of a static charge to the wire. He used synchronous rotation of lettered dials at each end of the line, and charged the wire at the sending-end whenever the letter to be indicated passed an opening provided in a cover; the electrometer at the far end then diverged, and thus informed the receiver of the message which letter was designated by the sender. The dials never stopped, and any slight want of synchronism was corrected by moving the cover. Hughes' printing instrument is the fully developed form of this rudimentary instrument. A gas pistol was used to draw attention, just as now a bell is rung. The primary idea of reverse currents is to be found where Sir Francis suggests that the wire when charged with positive electricity should discharge not to earth but into a battery negatively charged. Equally interesting is the discussion on what we now call lateral induction, then known as compensation. The author clearly saw that in the underground wires which he suggests as substitutes for aerial lines, this induction would be or might be a cause of retardation. His own words must here be quoted:—"That objection which has seemed to most of those with whom I have conversed on the subject the least obvious, appears to me the most important, therefore I begin with it, *viz.*, the probability that the electrical compensation, which would take place in a wire enclosed in glass tubes of many miles in length (the wire acting, as it were, like the interior coating of a battery) might amount to the retention of a charge, or, at least, might destroy the suddenness of a discharge, or, in other words, it might arrive at such a degree as to retain the charge with more or less force, even although the wire were brought into contact with the earth." This passage, written in 1823, is very remarkable, and would alone entitle the author to be mentioned in any history of underground or submarine telegraphs. Testing-boxes were invented by Sir Francis, and a code is suggested by him. If these things had been mere suggestions they would have been remarkable, but accompanied by practical experiments proving that the scheme could be carried out, they ought to connect his name permanently with the history of the Electric Telegraph. F. J.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Oceanic Circulation

ON returning from my second Mediterranean cruise, I find that Mr. Croll has published in the *Philosophical Magazine* his promised demonstration of the theoretical impossibility of the production of under-currents by gravitation, according to the doctrine which I have advocated with reference to—

1. The Gibraltar Current.
2. The Baltic and Black Sea Currents.
3. The General Oceanic Circulation.

At the same time I find awaiting me a very important treatise

* *E.g.*, The "Neotropical Region" of Sclater, *i.e.*, South and Central America, is divided between two "realms," an "American Tropical" and a "South American Temperate," than which nothing can be more unnatural, and North America is parcelled out into "three realms!"

on the Physics of the Baltic ("Untersuchungen über Physikalische Verhältnisse des Westlichen Theiles der Ostsee") by Dr. H. A. Meyer, of Kiel, containing the results of a continuous series of most careful and systematic observations on the temperature, specific gravity, and movement of the different strata of its water, dating back to the spring of 1868. With this work I received a letter from its author, of which the following extracts will, I think, be interesting to your readers:—

"I have followed with special attention the splendid results of your different voyages, and hope that the experience which I have gathered on a more confined area may yet offer something which you may deem worth your attention. The favourable opportunity which I enjoyed for continuing regular observations at a spot where the waters of the North Sea mingle with those of the Baltic, enabled me to collect matters which cannot be brought together on sea-voyages only; and I should be much pleased to see similar work undertaken at Gibraltar and Constantinople. If among your large circle of acquaintance you might know of gentlemen who may be interested in this cause, I should be happy to send them my book.

"I regularly read NATURE, and am much surprised to find that your views on Ocean-currents should not be universally accepted. How one can suppose that such a vast force which constantly acts in one direction should remain without any influence whatever, is perfectly incomprehensible to me!

"Most probably the cold under-current coming from the pole will be—wherever it is not very confined—very slow; but I doubt not that, should you consider it of sufficient importance, you will succeed in proving that the current, when confined, is pretty fast, that is to say, fast enough to be measured by the instrument which you used in the Straits of Gibraltar.

"With a similar appliance, which I have used for years, and which you will find figured in my work, I have lately been able to trace the heavier under-current in the Baltic to a much greater distance. On board one of the despatch boats of the German Navy, accompanied by some friends, I have this summer made several trips through the Cattegat and Skager Rack, and into the eastern parts of the Baltic; and my views have been everywhere confirmed."

I have further to state that my prediction that a similar under-current of dense water must pass through the Dardanelles and the Bosphorus from the Ægean into the Black Sea, which, it has been alleged by Captain Spratt, is disproved by experiments made by him several years ago, is regarded by three of the ablest of our Hydrographers to be conclusively proved by those very experiments when rightly interpreted. This I shall shortly demonstrate in an appendix to the forthcoming Report of my recent cruise.

The case between Mr. Croll and myself, therefore, stands thus:—

1. I have experimentally proved the existence of an *outward* under-current in the Straits of Gibraltar, and have adopted the gravitation theory of Captain Maury as affording an adequate account of it.

2. I have shown that this gravitation theory is applicable, *mutatis mutandis*, to the converse cases of the Baltic and Black Sea *inward* under-currents, the existence of which has been experimentally demonstrated.

I have further shown that it is applicable to that general Oceanic Circulation, the evidence of which appears to me to be afforded by the aggregate of observations that indicate the prevalence of a temperature not far above 32° on the deep ocean-bottom, even under the equator, and by the intermediate soundings which indicate the existence of two distinct strata, separated by a "stratum of intermixture," in parts of the deep ocean which the Gulf Stream assuredly does not reach.

These views have been accepted by Physicists of the highest eminence; but, as Mr. Croll affirms, without due consideration of their theoretical difficulties. I venture to suggest, however, that it is not beyond the range of possibility that Mr. Croll's data may be erroneous; and I do so with the more confidence, because I have been assured by first-rate Mathematicians that the science of Hydro-dynamics has not yet attained a development which would justify the assertion, that (to use Dr. Meyer's words) "a vast force constantly acting in one direction remains without any influence whatever."

It happens that I very early became impressed with the power of very small differences in Temperature to produce currents in liquids, by the following remarkable fact, which has never (so far as I am aware) been published. More than thirty years ago Mr. West of Bristol (where I then resided) built an observatory

on Clifton Down, the principal instrument of which was intended to be a refracting telescope of large aperture, the object-glass of which was to be made on the plan of Mr. Peter Barlow; the double concave of flint being replaced by sulphuret of carbon, or some other liquid of great dispersive power. The object-glass was constructed with the greatest care, Mr. Barlow kindly assisting in the computation of the requisite curves; but when tried it was found to be practically useless, in consequence of the movement produced in the liquid by the very minute differences of temperature occasioned by air-currents striking the surface of the outer lens.

I would also direct the attention of your readers to the very interesting paper by Prof. Karl Möbius, the coadjutor of Dr. Meyer, "On the Source of the Nourishment of the Animals of the Deep Seas," of which a translation will be found in the "Annals of Natural History" for September. Careful and prolonged observation of the movements of organic particles in aquaria satisfied him that very slight changes of temperature have a very important effect in producing changes in the stratification, so to speak, of the water; in one instance, he says, "a downward current, which readily carried organic bodies along with it, was produced when the difference between the superficial and bottom temperatures had scarcely attained half a degree of Reaumur (1° Fahr.)."

Such being the facts of the case, and Mr. Croll having offered no explanation of them, whilst demonstrating to his own satisfaction that the explanation I advocate is untenable, I do not feel called upon to discuss the subject further. There can be no reasonable doubt that, within the next few years, a great mass of additional data will be collected, which will afford adequate materials for the construction of a definite Physical Theory, by Mathematicians fully competent to the task. At present I do not pretend to have done more than offer a hypothesis which accords with the facts at present known, and with what Sir John Herschel called the "common sense of the matter."

Nov. 14

WILLIAM B. CARPENTER

The Solar Parallax

IF Mr. Proctor had printed in full my memoranda on the errors and imperfections of his history of the solar parallax, or if he had said nothing about it, I should have said nothing more in defence of my review. But, in NATURE of September 28, he gives so inadequate an account of my notes, hiding the point of the most remarkable of his inaccuracies, and ignoring the imperfections entirely, that I am compelled in self-defence to explain. In describing the various discussions of the Transit of Venus which preceded that of Mr. Stone, he says (p. 61): "Newcomb, of America, was more successful. He deduced the value 8''.87 by a method altogether more satisfactory than Poulkowsky's. But still the agreement between the different observations was not so satisfactory as could be wished, nor had Newcomb adopted any fixed rule for interpreting the observations of internal contact, which, as I have said, are affected by the peculiar distortion of Venus's disc at that moment."

To express my appreciation of this compliment it is only necessary to say that I have no recollection of having discussed the past transits of Venus at all, beyond correcting what I supposed to be an oversight in Mr. Stone's paper, and I am still utterly at a loss to know on what ground the compliment is based. In his letter he tries to throw the responsibility upon an anonymous correspondent of the Astronomical Register, which I regret to say does not circulate here, but he does not quote anything to justify a single statement in the preceding paragraph. The correspondent says nothing about 8''.87, which, it will be noted, is Mr. Petrie's pyramid value, nor about my treatment of contacts, so far as quoted by Mr. Proctor, so that I am as much in the dark as ever.

We have all heard suspicions that critics sometimes review books without reading them, but this is the first time I remember to have seen so circumstantial a description of a work which never existed, save in the writer's imagination. I really cannot help viewing it as something "remarkable" when coming from a writer of Mr. Proctor's accuracy and erudition, and must be pardon if I measure his writings by too high a standard.

The imperfections consist briefly in the regularity with which the more recent and complete researches on the solar parallax are ignored, incorrectly given, or placed in the back-ground of older and less complete ones. If any one wants to satisfy himself of this, he has only to look at the papers and discussions which have appeared in the *Comptes Rendus*, the *Monthly Notices*, and

the German "Vierteljahrsschrift des Astronomischen Gesellschaft" within the past four or five years, and see that only a single one of them all is expressly mentioned, and to note the values of the parallax adopted in the astronomical ephemerides of France, Spain, Portugal, and Germany, and see that not one of them can be traced in Mr. Proctor's history. If, as he once said, he had not room to describe the recent researches, I should have supposed he would have condensed or omitted the older ones, which these recent ones have superseded, instead of doing the contrary. The importance of this matter arises from the fact that these discussions and researches put a different face on a number of questions connected with the determination of the solar parallax from that given by Mr. Proctor, and I do not think the latter can successfully argue that the astronomical world of to-day is nearly all wrong in the views to which it has been led by five years of discussion, experiment, and research.

On Nos. 3, 4, and 7, of Mr. Proctor's defence, it is only needful to remark (1) that I did not write No. 3 till I had verified Foucault's result by a careful calculation not made on my thumb-nail; (2) that Mr. Proctor leaves it to be logically inferred that the discussion alluded to in No. 4 was an unpublished one; (3) that, having disclaimed my interpretation of No. 7, his book gives no explanation of the reason why Mr. Stone's parallax was so much greater than those of Encke and Ferrer. It is only necessary to refer to the paper of the latter in vol. v. of the *Memoirs of the Royal Astronomical Society* at pages 254 and 264 to find a very full discussion of the apparent, and the so-called true contacts.

No. 6 involves one of the most important questions connected with the determination of the solar parallax from transits of Venus, and I am sorry to see that Mr. Proctor simply evades the issue, as the misinterpretation to which he refers consists in supposing him less erroneous than he really is. Let one make a drawing representing the limbs of Venus and the sun in mathematical contact. On each side of the point of tangency there will be an exceedingly thin thread of light, vanishing at that point. How much of this thread will be visible by an ordinary telescope? We must remember that the sun is viewed through a dark glass, which reduces its light to that of an ordinarily illuminated object. The narrowest visible line so illuminated subtends an angle of about $20''$. With a power of 120 this would correspond to a breadth of one-sixth of a second. But it is well known that atmospheric tremors, and, with most old instruments, imperfect corrections of the object-glass, prevent our seeing an object at all approaching the minimum visible, and that the same cause prevents the increase of magnifying power from giving a corresponding increase of seeing power. It is probable that the thickness of the least visible thread may have varied with the telescope, the observer, the dark glass, and the atmosphere, from one or two tenths of a second to one or even two seconds. Let us take the more favourable cases in which a thread of $0''.2$ is visible. A simple calculation will show that there is a space of $3''.4$ on each side of the point of tangency, in which the thread will be thinner than this, and therefore invisible, and that the visible cups will be about $7''$ apart. How different this $7''$ from Mr. Proctor's invisibly thin ligament! This explains the observations of Wolf and André, who found that the black drop when seen at all continued after internal contact at ingress and preceded it at egress.

In answer to Mr. Proctor's letter of October 5, I beg leave to reply, if the "fringe" is something actually produced by the telescope or the atmosphere, it is simply bad definition. If it is not so produced, it is an optical illusion, of which the laws are obscure, and the very existence problematical under the circumstances in question. See, for instance, the celebrated paper of Prof. Baden Powell on Irradiation. Mr. Proctor's intimation that the great mass of astronomers who have observed transits of Mercury within the past forty years, among whom are included Bessel, Airy, and the Struves, were careless and inferior observers, because they did not see an optical illusion according to his view of it, is as good a *reductio ad absurdum* of his theory as I could ask for. It is comforting to know that one of his careless observers can be turned into a careful and attentive one by giving him a telescope with plenty of irradiating power.

To prevent misapprehension, allow me to say that the theory set forth in my letter of September 28 is in no way my own, but was promulgated by Bessel nearly forty years ago, and has, I believe, been since universally received on the continent of Europe.

Washington, Oct. 23

SIMON NEWCOMB

The Aurora of Nov. 9th and 10th

I WITNESSED on the night of Nov. 9, at about 7.30 P.M., an aurora which, for symmetry of form and other features, was very remarkable; and unless, as is very likely, some more able observer has already sent you a description of it, you may like to put my account on record.

In the magnetic north horizon was the usual segment of auroral light, very brilliant, and stretching considerably to the east and west, its altitude being 20° or more. High above this, and extending in a complete arch from the east to the west horizon, was a remarkable and well-defined band of still brighter light, about $7''$ in breadth, and passing about $30'$ from the zenith.

Filling the space between these two arcs of light was what I can call nothing else than a dark shadow, which had somewhat of a mysterious appearance; for, though decidedly darker to the eye than other parts of the heavens, it did not in the least obscure even small stars, nor do I think this darkness was the effect of contrast. In this dark space faint auroral streamers occasionally shot up to the upper arch, but did not pass it. This shadow was what the French observers speak of as the *nuée*.

The light of the upper arched band was silvery, and increased much in intensity towards the horizon both east and west; the points of greatest intensity being about $5'$ above the horizon, as would be expected in the direction in which the arch appeared most foreshortened.

While watching this phenomenon I was impressed by the conviction that, to an observer in space, the north magnetic pole of our planet would have presented the appearance of being surmounted by a symmetrical cap of light, streaked by one or more bands, and terminated at its greatest distance from the pole by a well-defined brilliant margin.

In the hope that an observer in some other locality might have made similar observations, I was preparing to measure the distance of the upper arch of light from the zenith, as well as the positions in azimuth of the points where it touched the horizon, when the whole phenomenon was obscured by dense clouds.

Stretton Rectory, Hereford, Nov. 15

H. C. KEY

THE following brief extract from our observatory note book may be interesting:—

"Nov. 10.—For about 20° on each side of north, at 9.30—9.40 P.M., brilliant *curves* of light followed one another rapidly, from two to four in a second, moving upwards, following the direction of the streamers, fading away at about $40'$ from the horizon. Three or four waves could be seen at once, measuring about $5'$ to $8'$ by estimation, from crest to crest. . . ."

I heard some of the boys remark "How close it must be; it looks like puffs of steam from behind those houses."

Rugby

J. M. W.

As none of your correspondents who described the brilliant aurora of Nov. 9th and 10th last week, speak of their being seen earlier than from 7 to 10 P.M., it may be interesting to note that in the Midland Counties the latter was visible at a considerably earlier period of the evening. On the evening of the 10th I was walking from Reading in Berkshire to Caversham in Oxfordshire, from 5.45 to 6.5 P.M. During the whole of that time I had before me the steady *white* light of the coming aurora, extending perhaps $25'$ to $30'$ in width, and $20'$ in height, its centre being immediately beneath Polaris. The appearance was exactly that of the departing twilight in a clear winter sky, for which, indeed, but for its position and the time of the evening, it would have been mistaken. As I noticed the light immediately on leaving the railway station above the lights of the town, I have little doubt that it had been visible since sunset. I had no opportunity of watching its progress after 6.5 P.M.; up to that time there were no coloured streamers, nothing but the white light I have described.

ALFRED W. BENNETT

The Ghost of Flamstead

I OUGHT earlier to have thanked this venerated shade for a communication which will enable me to correct (at some future time) an omission in my treatise on the Sun. Let me hasten to

assure him (or it), however, that the omission has been in no way connected with those "queer notions of honour, and justice, and fairness," which he conceives to be rife in our times. Why should I seek to wrong the honoured dead? And who would gain in this case by the injustice? The present Astronomer Royal? Surely no. To add this small matter to his real claims to our esteem would be

To gild refined gold, to paint the lily,
And throw a perfume on the violet.

Neither, I am sure, has any other writer who has overlooked Flamsteed's claims, desired to do him injustice. On this point I would merely remark, "Rest, rest, perturbed spirit."

But now "we'll shift our ground," by the Ghost's good leave. Our visitor from Valhalla remarks that "a stir was lately made about what was represented as a new method of investigating the motion of the solar system in space, and instead of a new there was brought forward an old acquaintance (known to Science since the times of our grandfathers)." Here the spirit of Flamsteed refers obviously to the Astronomer Royal's method. I am sure that Prof. Airy would desire greatly that if his method be indeed so ancient, the fact should be made widely known. I myself am particularly anxious to be set right on this point, about which I am at this very time writing. For though I care more about explaining this and the other methods than about their history, yet it is desirable to be accurate even in historical details.

If I may say so without offence, I would remark that a ghost was not needed—certainly not the ghost of the first Astronomer Royal—to teach astronomers that the opposition of Mars in 1877 will be exceptionally important. At page 25 of my "Sun" I have already pointed this out, and I dare say others have done likewise.

I hope the "great injustice" to which our ghostly correspondent refers as endured by him in life, does not relate to his difficulties with Newton, for at the present time the opinion of Brewster on this point is in vogue—not Bailly's; and the warmest admirers of Flamsteed are those who least desire to moot the subject.

R. A. PROCTOR

Brighton, Nov. 4

Creators of Science

PERMIT me to do my little towards clearing up a most unfortunate confusion of thought respecting the intellectual ranks of mathematicians and metaphysicians, which is, in my experience, widely prevalent. We may safely divide the mathematicians into three orders:—(1) Inventors, (2) Experts, (3) Readers or Students, so as to discriminate from one another those who create systems, those who manipulate with them, as "ministers and interpreters of nature"—just as easily and familiarly as Professor Tait (*e.g.*) employs and applies the theory of Quaternions—and those who have merely studied into an understanding of an author or subject. It was an expedient of the late Sir William Stirling Hamilton to confound all these orders, and from the heterogeneous lump to extract—if not extort—testimonies to the worthlessness of mathematics as a mental discipline, without the least discrimination of their sources.

On the other hand, the metaphysicians cannot be trichotomised; for, even in the present advanced state of metaphysics, there is no class of philosophers corresponding to the mathematical experts, the reason of which explains why examiners in mental science do not set problems. There are, in fact, only two classes of metaphysicians: I., Creators; II., Students, more or less thoroughly versed in the systems of the leaders, and more or less accepting or rejecting, with more or less reason, those creations. Accordingly, when on May 17, 1869 (I think that was the date), Professor Tait, at a meeting of the Royal Society of Edinburgh, challenged the metaphysical world to produce a metaphysician who was also a mathematician, he not being able at the moment to call to mind a single instance, he was to be understood as asking for a person of the order I, who was also in the class I. Professor Calderwood's reply, then, was not wholly unexceptionable, for of the three names he adduced, viz., Descartes, Leibnitz, and Hegel, the last was that of a reader of mathematics, and not of a mathematical inventor. The challenger might have spared the respondent the trouble of reply, had he known what De Morgan wrote in Notes and Queries, 2nd S. vi. 293-4, where are distinguished five mathematical inventors, as *factors principis*: viz., Archimedes, Galileo, Descartes, Leibnitz, and Newton; and in which Aristotle, Plato, and D'Alembert are allowed a very high rank in mathematics. Had the inventor of Quaternions been then dead, I have little doubt that De Morgan would have

added to the five the name of Sir William Rowan Hamilton, who, besides being a mathematical inventor of the very first rank, was also a diligent and accomplished student of Plato, Kant, Reid, and the other Hamilton, and a writer on Logic; i.e., as good as D'Alembert as a philosopher, and perhaps better than he as a mathematician. Now, it is not a little curious and very instructive to observe that, *pace Platonis*, the two who were creators of strictly defined metaphysical systems, viz., Descartes and Leibnitz, are the only two among the five metaphysicians adduced by De Morgan who belong to the highest rank as mathematical inventors.

It is quite incredible that a man of Professor Tait's learning (I say here nothing of his judgment) should not have been aware of the identity of Descartes (the poor dreamer!) and Cartes, the founder of the Cartesian Geometry; still more so that he should not have known that the immortal analyst, the co-inventor of the Differential Calculus, was the most eminent metaphysician native to Germany before Kant. It was, then, not "ignorance," but "ignorance," on the part of the Scotch mathematician, that was involved in his challenge; and that challenge was doubtless intended as mere *badinage*, at the expense of a science which he had taken no pains to understand.

Be that as it may, I trust I am not singular in adjudging (as De Morgan did) these two grand intellectual pursuits to be worthy of being cultivated together, and to be able to give material aid to each other. For myself, I cannot but look upon any man as the enemy of intellectual progress, who delights in setting the one class of investigators against the other, and endeavours to prolong the controversy which has raged between them since the "Principia" was promulgated.

Highgate, Nov. 8

C. M. INGLEBY

Descartes' "Animated Machines"

AS you open your valuable columns to philosophical discussions, may I request you to publish the following remarks on a passage in Mr. Lewes's popular "History of Philosophy" (Vol. ii. p. 148 of the new edition), where he confesses himself puzzled, along with other critics, to account for Descartes' theory that animals were only *animated machines*. "I am not prepared," he says, "with a satisfactory explanation." I cannot but think that a careful perusal of the "Discourse on Method" (Part 5, *sub. fin.*) and of the treatise on *Les Passions de l'âme*, makes Descartes' reasons perfectly clear. In the first place, the use of the word *machine* has misled most of his critics, and if the story of Malebranche and his dog be true, even this great disciple had grievously mistaken the principles of his master. For in the last-named treatise Descartes endeavours to show that such feelings as joy, grief, fear, &c., though in us accompanied by really mental acts (*pensées*), are produced by physical causes, and produce physical effects apart from the mind. Descartes would therefore never have denied to brutes any of the bodily sensibilities which we possess; and says expressly that he calls them machines in a special sense—machines made by the Deity, and therefore infinitely more subtle and perfect than any which we can construct. He says that we could not ourselves be ranked higher in the scale of beings did we not possess the gift of *language*, the phenomena of which can only be accounted for by an internal principle different in kind from those which appear to guide the lower animals, though there are also those passions in us which we have in common with them.

But to come to the psychological reasons for the theory. Historians of philosophy before the 18th century should be particularly alive to theological *idola*, even in sceptical writers; much more so in good Catholics like Descartes. Just as Berkeley put forward prominently the theological advantages of his Idealism, so Descartes indicates plainly in his "Discourse on Method" (*loc. cit.*) that these were the chief reasons of his theory. "Next to the error of those who deny the Deity, which I have already refuted, there is none more apt to seduce feeble minds from the path of *virtue* than to imagine that the soul of beasts is the same as ours." But the *locus classicus* has, I think, escaped Mr. Lewis, and will be found in a letter to a Lord (supposed to be the Duke of Newcastle), the 54th of the 1st volume in the original quarto edition. Descartes there specially answers objections made to him on this point, and in the way above indicated; adding, however, the following passage: "Yet it may be said that although the beasts perform no action which convinces us that they think, nevertheless, as the organs of their bodies do not differ much from ours, it may be conjectured that some sort of thought is joined to these organs, such as we experience in ourselves, but much less perfect;

to which I have no reply to make, except that if they thought as we do, they must have an immortal soul as we have, which is not likely, as we should apply the argument to all animals, such as sponges, oysters," &c. I am sure these ideas are not unfrequently repeated in his correspondence, as for example, in one of his replies to Morus (vol. i. No. 67 of the 4th edition, in Cousin's Edition, x. p. 204 *et seq.*). He there even talks of two souls, an *âme corporelle* which is the cause of passions and affections, and an incorporeal principle of thought, which he elsewhere says was infused by the Deity into man at the first moment of his existence. He also observes, I think logically enough, that as no boundary line can be drawn elsewhere, we have no choice between conceding a soul to oysters or refusing it to all animals save man. I am not however concerned to defend the validity of his reasons, but rather to contribute this information as an historical point of interest.

Trin. Coll., Dublin, Nov. 11

J. P. MAHAFFY

Plane-Direction

I THINK "plane-direction" is the best of the competing names. The planes of cleavage in a crystal are the "plane-directions" in which it is most easily split. They cannot be called either "aspects" or "positions." The opposite faces of a cube certainly cannot be said to have the same "aspect."

If a rigid body receives a movement of translation, it retains something unchanged. What is this something to be called? It might be called "lie" or "set," but both names are equivocal. Two equal and similar figures possessing this something in common might be very well described as "similarly laid," "similarly set," or "similarly placed." We may say that they have "similar positions," but we can scarcely say that they have "the same position;" for change of position is commonly held to include movements of translation as well as of rotation, and a point is usually defined as having position but not magnitude. I think it is worth while to consider whether "position" cannot be restricted to the more limited sense, "place" being employed in the wider sense.

I wonder that no one has yet raised a murmur against the proposition itself, which your correspondents are so anxious to render literally into English. It appears to me that the plain English form in which Mr. Wilson first stated it is clearer and more precise than the German abridgement. In the strictest sense of "determine," one "Richtung" determines one "Stellung" and one "Stellung" determines one "Richtung," inasmuch as to one plane-direction there corresponds one normal direction.

In a special sense it is true that two "Richtungs" determine a third (perpendicular to them both), and that two "Stellungs" determine a third (also perpendicular to both); just as two points may be said to determine one plane (bisecting their joining line at right angles). In all these instances the fact is that not one only but many are "determined," but all except one come out in pairs or multiples of two. It is this one, which has no fellow, that is in a special sense "determined."

I think it is paradoxical and misleading to state, without qualifying words, that two linear directions determine one plane-direction; inasmuch as two linear directions really serve to define as many different pairs or multiple pairs of plane-directions as we please, and if we are permitted to distinguish the two linear directions by different names, three plane directions can be separately defined by them without any ambiguity. Similar remarks, of course, apply to the other half of the proposition.

J. D. EVERETT

Rushmere, Malone Road, Belfast, Nov. 11

"Wormell's Mechanics"

WILL you do me the favour of inserting a brief reply to the few remarks made concerning the above text-book in last week's NATURE?

1. On page 8 of the book occurs an explanation of what is usually termed the transmissibility of force, and a statement of the axiomatic principle that we may imagine a force to be applied at any point in the line of its direction, *provided this point be rigidly connected with the first point of application*. On page 14 a deduction from this principle is made and employed to prove

the rule for finding the directions of the resultant of two forces acting on a point. The reviewer says that this deduction, "if true, would assert that the attraction of the sun and the earth upon the moon might be transferred to any heavenly body in space which happened to be in the line of direction of the resultant of the forces." If the restriction laid down with emphasis in the book, and printed in italics as quoted above, be not ignored, this is a legitimate inference, and if the point to which the forces are transferred parallel to themselves be rigidly connected with the moon, any conclusion having reference to the magnitude or direction of the resultant action on the moon derived as a consequence of the imaginary transposition of the point of application of the forces will be correct.

2. In finding the direction of the resultant of two parallel forces, the same transposition of the point of application is employed, and, of course, it is understood with the same proviso. This proof your reviewer qualifies as "meaningless," whereas I feel sure that, taken in connection with the original axiom and the deduction above referred to, it would be accepted by any mathematician as both intelligible and correct.

3. The next statement is that the definition of a rigid body is given as a property of forces. This is not so, but the whole theory of statics, when developed independently of dynamics, rests on the properties of a force and the properties of a rigid body jointly.

4. The reviewer next dwells upon a curious error which unfortunately escaped my notice until it was pointed out but a short time ago by a schoolboy, and which forms one of three corrections on a slip of errata. Any student would, however, have been able to make the correction for himself by the help of the preceding pages and the applications to the following exercises, a circumstance which I think an unprejudiced critic should not have overlooked.

5. Your reviewer next remarks that a student who tries an experiment with a block and tackle would naturally be surprised at finding that the result of experiment does not agree with that of the theory, and adds, "nor can we find a single word in the book which would enlighten his difficulty." The reviewer cannot have read section 71.

6. The subjects included in the book are such as comprise the course described in the curriculum and examination papers of the University of London, and if occasionally the discussion of unpractical arrangements of mechanical powers is required, I am not answerable. Indeed, I hope to see the day when a reform of this part of the curriculum will necessitate my rewriting the work on an entirely different plan, namely, one according to which kinematics forms the first part, kinetics the second, and statics the third, the propositions of the third part being special cases of those of the second. But that at present it answers the purpose for which it is intended, is proved by the fact that all the questions set this year can be answered from it.

So far as most of the facts and illustrations are concerned, "I am but a gatherer and disposer of other men's stuff," and a writer of an elementary text-book to suit the requirements of a particular examination could not easily be more.

The tone of deprecation with which the writer of the article has been pleased to refer to the work, so directly opposed to a previous notice of the same book in the same journal, seemed to me to call for some reply, and I should wish to describe more fully the objects I have aimed at in compiling the work, but that I know I have already taken up enough of your valuable space.

RICHARD WORMELL

ONE OF THE GREATEST DIFFICULTIES OF THE DARWINIAN THEORY

SIR JOHN LUBBOCK has done good service to science in directing attention to the metamorphoses of insects, by admitting freely the great difficulty in conceiving "by what natural process an insect with a suctorial mouth, like that of a gnat or butterfly, could be developed from a powerful mandibulate type like the Orthoptera, or even from that of the Neuroptera" (NATURE for Nov. 9, page 28). Such "difficulties" have struck many from the first, and it is in no small degree encouraging to those who love the liberty of science, to find that the time is ap-

proaching when difficulties may be brought under consideration and discussion.

"There are," Sir John Lubbock remarks, "peculiar difficulties in those cases in which, as among the Lepidoptera, the same species is mandibulate as a larva, and suctorial as an imago." The power of mastication during the first period of life being an advantage, on account of a certain kind of food being abundant, and that of suction during the second, when another kind of food prevailed, or *vice versa*, is suggested as a possible explanation of the origin of species which are mandibulate during one period of life and not during another. In such cases it is said we have "two forces acting successively on each individual, and tending to modify the organisation of the mouth in different directions." It is suggested that the change from one condition to the other would take place "contemporaneously" with a change of skin. Then it is urged that even when there is no change of form, the softness of the organs precludes the insect from feeding for a time, and when any considerable change was involved, "this period of fasting, it is remarked, would be prolonged, and would lead to the existence of a third condition, that of pupa, intermediate between the other two."

There is much that is assumed in this reasoning; but I shall now venture to call the attention of naturalists to one point only, namely, the analogy between the period of fasting caused by the temporary softness of the organs while the caterpillar changes its skin, and the more prolonged fasting period when the organs undergo that more considerable (!) modification involved in the change from the mandibulate to the suctorial type of mouth. The change from a small mandibular apparatus to a larger one seems to be compared with the change from a mandibular to a suctorial apparatus—the change of skin of the caterpillar with the change of skin when the caterpillar becomes the pupa, and the latter the imago—the temporary softness which prevails when the little mandibles grow into bigger mandibles, with the temporary softness which prevails while the mandibles become converted (!) into the suctorial mouth. But these changes are surely of different orders, and the operations of a different nature. The mandibles do not change. The one type of mouth does not pass through gradations of any kind into the other kind of mouth. But one abruptly ceases, its work having been discharged, while the other is developed anew. As compared with the change of skin of the caterpillar, the change of skin from chrysalis to butterfly is indeed a "*considerable change*." It would require an amazing intelligence to premise from the study of a caterpillar that from it, after certain changes of skin and periods of rest, would emanate a butterfly.

It is very well to suggest that "in reality the necessity for rest is much more intimately connected with the change in the constitution of the mouth"; but what, I would ask, is the evidence of the connection implied? Between the *change* from the small mandibles to the large, and the *change* from the latter to the suctorial apparatus, there can be no comparison—no analogy, for the suctorial mouth is developed anew during the pupa state, and its formation is not commenced until all traces of the mandibles are gone. Nay, every tissue of the caterpillar disappears before the development of the new tissues of the imago is commenced. The muscular and nervous systems of the latter are as different from those of the former as are the digestive apparatus, the oral mechanism, and the external covering. These organs do not change from one into the other; but one, having performed its work, dies, and is removed entirely. Not a vestige of it remains. Its place is occupied by formless living matter, like that of which the embryo in its early stages of development is composed; and from this *formless matter* are developed all the new organs so marvelously unlike those that preceded them; and others unrepresented at all in the larval stage, make their

appearance. To explain, according to Mr. Darwin's theory, the "period of change and quiescence" intermediate between the caterpillar and imago states of existence, is likely to remain for some time a very difficult task. If the difficulty cannot be resolved until the period of quiescence during which the imago is formed, is proved to be analogous to the periods of quiescence during the change of skin of the larva, the life history of a butterfly will remain for a long time a puzzle to Mr. Darwin and those who believe in the universal application of his views.

LIONEL S. BEALE

ON THE RECURRENCE OF GLACIAL PHENOMENA DURING GREAT CONTINENTAL EPOCHS

IN the August number of the Geological Society of London I published two papers "On the Physical Relations of the New Red Marl, Rhaetic Beds, and Lower Lias," and "On the Red Rocks of England of older date than the Trias." In the latter I attempted to prove that for the north of Europe and some other parts of the world, a great Continental epoch prevailed between the close of the upper Silurian times and the end of the Trias or commencement of the deposition of the Rhaetic beds; in other words, that the Old Red sandstone, Carboniferous strata, Permian beds, and New Red series were chiefly formed under terrestrial conditions, all, with the exception of the Carboniferous series, in great lakes and inland seas, salt or fresh.

The Permian strata, in particular, appear to have been deposited under conditions to which the salt lakes in the great area of inland drainage of Central Asia afford the nearest modern parallel.

While brooding over the whole of this subject for several years past, I have often been led to consider its bearing on those recurrent phenomena of glacial epochs which now begin to be received by many geologists.

The phenomena of moraine-matter, scratched stones, and erratic boulders, whether deposited on land by the agency of glaciers, or in the sea and lakes by help of floating ice, are evidently intimately connected with the contemporary occurrence of large areas of land, much of which may, or probably must, have been mountainous.

The late Mr. Cumming, in his History of the Isle of Man, "hints at the glacial origin of certain Old Red conglomerates in that island, conceiving that the bony external skeletons of some of the fish of the period may have been provided to enable them to battle with floating ice. In lectures and in print I have frequently stated my belief that the brecciated subangular conglomerates and boulder beds of the Old Red sandstone of Scotland and the north of England are of glacial origin, so distinct, indeed, that when these masses and our recent boulder clay come together, there is often actual difficulty in drawing a line of demarcation between them. I frequently felt this difficulty years ago, when, commencing the Geological Survey of Scotland, I mapped the strata in the country south of Dunbar, and the same difficulty was occasionally felt by others in the valley of the Lune, near Kirkby Lonsdale.

If, as I believe, the Old Red sandstone was deposited in inland Continental waters, the Grampians, as a mountain tract, bordered these waters, and they must have been much higher then than now; not only because of the probably greater elevation of the whole continent, but also because the Grampians formed land during the whole of the Upper Silurian epoch, and suffered great waste by denudation, then and ever since. The glaciers of these mountains marked an episode in Old Red sandstone times, and yielded much of the material of the boulder beds of the Old Red sandstone.

In these regions and in North America, the Carboniferous

strata were evidently formed under the influence of "a warm, equable and moist climate," and I know of no glacial phenomena in connection with this epoch.

But respecting Permian times I attempted in 1855 to prove the existence of ice-borne boulder beds during part of that epoch, and by degrees this opinion has been more or less adopted. These boulder beds were derived by glacial transport from the mountains of Wales, which then, also, were necessarily much higher than now. As the Old Red boulder beds were formed during a glacial episode or episodes of parts of that epoch, so the Permian boulders mark another glacial episode occupying part of Permian time, just as our last great glacial epoch formed an episode in those late Tertiary times of which the present time forms a part. At the time of the publication of this paper, I conceived the Permian boulders to have been deposited in the sea by the agency of icebergs, but I now consider them to have been deposited in inland lakes.

This, if true, formed a second glacial epoch, of unknown intensity, during the long continental period that lay between the close of Upper Silurian and the beginning of Liassic times.

During the Triassic period there is no certain sign of glacial phenomena in the British area.

I have elsewhere attempted to show that at the present day there is an intimate connection between past glacial phenomena and the occurrence of lakes, large and small, many of which are true rock-bound basins.

I further believe that this cause would be found to characterise ancient Continental recurrent glacial epochs through all past time, if perfect data were accessible, or had been preserved from destruction by denudation and disturbance of strata. In the Palæozoic cases mentioned above, there is, in my opinion, an evident connection of some kind between inland lakes and glacial action, and in stating this it must be borne in mind that I do not consider the Old Red and Permian strata of Britain to have been deposited solely in two lake basins during two epochs, but in various basins during each of two special eras of geological time. For example, the Magnesian Limestone beds of Yorkshire and Northumberland were formed in a hollow quite distinct from the great conglomerates (locally called "brockram") and sandstones of the Vale of Eden. Prof. Harkness in 1856* showed that in the South of Scotland Permian beds, partly formed of brecciated conglomerates, lie in rocky hollows entirely surrounded by lips of Silurian and Carboniferous strata, in fact, in rock basins; and he attributed this singular circumstance to a sinking in of the Silurian strata in each case underneath the Permian rocks.

Ever since the publication of my paper, in 1862, on the Glacial origin of certain lakes in rock basins, I have suspected that these Permian rock basins may also have been scooped out by the agency of glacier ice. I connect this view with my paper on Permian glaciers, published in the *Geological Journal* in 1855, but as I have not yet seen the country where these hollows lie, I have not been able either to verify or disprove this supposition. I expect, however, that some day this view will be proved, not for these areas alone, but for others of larger area and very different date, which as yet I have only partially examined, in other European countries.

The unravelling of nearly all stratigraphical phenomena of every geological age resolves itself simply into attempts to realise ancient physical geographies, and we may rest assured that those forces that are now in action have played their part in the world sometimes with greater, sometimes with less intensity, through all known geological time, as far as it can be studied by an examination of the rocks that form the crust of the earth. If glacier ice scooped out many lake rock-basins in the latest great glacial epoch, it did the same during glacial epochs of earlier date.

WOOD'S "INSECTS AT HOME"*

THIS bulky volume of 670 pages appears to us to be altogether a mistake. It is far too voluminous and too uninteresting for a beginner, while for the more advanced student it is almost valueless, being a very incomplete compilation from the works of well-known writers. It consists of brief and imperfect descriptions of a selection of, perhaps, one-twentieth of the insects inhabiting Great Britain, with occasional notices of their habits and economy, and extracts from a few entomological works. These descriptions are generally introduced by such words as "Our next example," "We next come to," "We now come to," "Next in order comes," "Next on our list is," &c. &c.; and for the most part are mere amplifications of short technical characters, conveying a minimum of useful information, with a maximum expenditure of words. Let us take two examples at random. At p. 76 we have two-thirds of a page devoted to a beetle:—

"Our first example of the Staphylinidæ is one of the finest, in my opinion the very finest, of that family. It is called scientifically *Crepophilus maxillosus*, but has, unfortunately, no popular name, probably because it is confounded in the popular mind with the common black species, which will be presently described. Its name is more appropriate and expressive than is generally the case with insect names. The word *Crepophilus* is of Greek origin, and signifies 'flesh-lover,' while the specific title, *maxillosus*, signifies 'large-jawed.' Both names show that those who affixed them to the insect were thoroughly acquainted with its character and form, for the Beetle is a most voracious carrion eater, and has jaws of enormous size in proportion to its body. The colour of this beetle is shining black, but it is mottled with short grey down.

"In some places this Beetle is tolerably plentiful, but in others it is seldom if ever seen. It can generally be captured in the bodies of moles that have been suspended by the professional mole-catchers, and, indeed, these unfortunate moles are absolute treasure-houses for the coleopterist, as we shall see when we come to the next group of Beetles. A figure of this insect is given on woodcut No. viii. Fig. 3. It is the only British insect of its genus which is distinguished by having short and thickened antennæ, smooth head and thorax, and the latter rounded."

The descriptive portion of this characteristic passage could be easily compressed into two or three lines. In the other twenty we are told that the original describers of the insect were well acquainted with it, that the public are not, and that moles caught by professional mole-catchers are unfortunate!

Turning to page 447, we have a moth described as follows:—

"The first family of the Geometræ is called Urapterydxæ, or Wing-tailed Moths, because in them the hinder wings are drawn out into long projections, popularly called 'tails.' In England we have but one insect belonging to this family, the beautiful, though pale-coloured, swallow-tailed moth (*Urapteryx sambucata*). The generic name is spelt in various ways, some writers wishing exactly to represent the Greek letters of which it is composed, and others following the conventional form which is generally in use. If the precisians are to be followed, the word ought to be spelt *Ourapteryx*.

"There is no difficulty in recognising the moth, the colour and shape being so decided. Both pairs of wings are delicate yellow, and the upper pair are crossed by two narrow brown stripes, which run from the upper to the lower margin. These stripes are very clear and well defined, but besides these are a vast number of very tiny

* "Insects at Home: Being a Popular Account of British Insects, their Structures, Habits, and Transformations." By the Rev. J. G. Wood, M.A., F.L.S., &c. With upwards of 700 Figures by E. A. Smith and J. B. Zwecker. Engraved by G. Pearson. (Longmans, Green, and Co. 1872.)

1. *Agabus biguttatus*. 2. *Hydrophilus duodecim-pustulatus*. 3. *Haliplus variegatus*. 4. *Cnemidotus caesus*. 5. *Pelobius Hermannii*.
 a. *Dytiscus*, process of metasternum. b. *Dytiscus*, maxillary palpus. c. *Dytiscus*, anterior leg of male. d. *Dytiscus*, labial palpi. e. *Gyrinus*, posterior.
 leg. f. *Gyrinus*, antenna.

1. *Microgaster glomeratus*. 2. *Mymar pulchellus*. 3. *Teleas elatior*. 4. *Cleonymus maculipennis*. a. *Teleas*, antenna, female. b. *Do.*,
 antenna, male. c. *Microgaster*, larva in caterpillar of cabbage-butterfly. d. *Microgaster alvearius*, cocoons.

DRAGON-FLIES, MAY-FLIES, AND CADDIS

1. *Ephemera vulgata*. 2. *Ephemera*, larva. 3. *Libellula depressa*. 3a. *Libellula* emerging from pupa-case. 4. *Libellula*, larva.
5. *Calopteryx virgo*. 6. *Agria minium*. 7. *Phryganea grandis*. 8. *Phryganea*, larva cases, or Caddis.

PLANTS:—Flowering Rush (*Butomus umbellatus*). In Centre. Mare's-tail (*Hippuris vulgaris*). On Right. Water Bistort (*Polygonum amphibium*). On Left.

streaks of a similar colour, which look as if they had been drawn in water-colours with the very finest of brushes, and then damped so as to blur their edges. The hind wings have only one streak, which runs obliquely towards the anal angles, and, when the wings are spread, looks as if it were a continuation of the first stripe on the upper

wings. The shape of the moth almost exactly resembles that of the Brimstone Butterfly, described on page 393.

"The larva affords an admirable example of the twig-resembling caterpillars. It is exceedingly variable in colour, but is always some shade of brown. It has seven bud-like humps, and a few pale stripes along the sides. I

is a very general feeder, and may be found, on a considerable number of trees and plants. It is quite common, and but for its curious form, would certainly be found much more frequently than is the case. The perfect insect appears about July, and can be beaten out of bushes and hedges. Though the wings are large, they are thin and not very powerful, so that there is no difficulty in capturing the insect."

Of course much of the book consists of more interesting matter than this, but hundreds of pages are filled with such verbose and meagre passages as those quoted, which are far more repulsive to the learner than the most condensed and technical description. Those given in Stainton's Manual, for instance, contain more than double the actual information in about one fourth of the space.

The book is illustrated by copious woodcuts in the letterpress and by several whole-page pictures. The former are most admirable, and do great credit to the artist, Mr. E. A. Smith. We select a group of Water Beetles (Cut vi.), and one of the minute and curious parasitic Hymenoptera (Cut xxxii.) as examples of these excellent figures, which would do credit to a far more scientific work. The whole-page illustrations are by another hand, and are in every respect inferior. Some of them contain fair representations of insects in their haunts, but the vegetation is generally badly drawn, and the plants said to be figured are often quite unrecognisable. The best and most artistic picture is Plate viii., representing a group of Neuroptera with aquatic vegetation. The worst is Plate xix., representing aquatic Heteroptera. The insects are pretty well drawn, but the plants are dreadful. One of them is said to be the Starwort (*Aster tripolium*). What is meant for this stands prominently out in the view; but the artist has evidently never seen the plant, and, trusting to his imagination to invent something suited to the name, has perched three thick six-rayed starfish on bending stalks. We venture to assert that no plant having the faintest resemblance to this monstrosity forms part of the British flora, and its introduction into a modern work on natural history is most discreditable. It is painful to have to speak in these terms of the work of an author who has done so much to popularise natural history as Mr. Wood, but we must protest against mere book-making; and in this case there could be no pretence of a want to be supplied, since the excellent series of "Introductions" published by Messrs. Reeve and the more general works of Prof. Duncan, Dr. Packard, and others, are far better guides to the student or to the general reader than such a hasty and imperfect compilation as the present volume.

A. R. W.

NOTES

THE Council of the Royal Society have awarded the medals in their gift for the present year as follows:—The Copley Medal, to Julius Robert Mayer, of Heilbronn; the Royal Medals to Mr. George Busk, F.R.S., and Dr. John Stenhouse, F.R.S.

PROF. ARCHIBALD GEIKIE is desirous of addressing himself through our columns to those of our readers who were friends and correspondents of Sir Roderick Murchison. They would much oblige and assist him if they would let him have the use of such of his letters as they can allow to be employed in the preparation of the biography which, at Sir Roderick's request, he has undertaken to write. If the documents are sent to him at Ramsay Lodge, Edinburgh, they will be returned at the earliest possible date.

FROM the English Government Eclipse Expedition we learn that since leaving Malta, on the evening of Saturday the 4th, the weather has been all that could be wished, and that Mr. Lockyer and the other members of the expedition have not failed to take all possible advantage of the calm weather in

testing their instruments and preparing themselves in every possible way for rapid yet correct observations during the few minutes over which the phenomena of the morning of the 12th December will extend. The *Mirzapore* commenced steering through the canal at 2.30 on the 8th, and anchored in Suez Roadstead at twelve on the 10th, all well. It was hoped that she might sail by daylight on the morning of Sunday, the 12th. In that case she might get to Galle by the 25th, and the Expedition would then have seventeen days at their disposal for arranging themselves and their instruments over the line of totality, from the north of Ceylon to the western shore of Southern India. The passage through the Canal has been a pleasant and interesting one.

THE Falconer Memorial Fellowship, at the University of Edinburgh, which is of the annual value of about 100*l.*, tenable for two years, has been conferred on Mr. William Stirling, B.Sc. The Baxter Physical Science Scholarship, vacant by the appointment of Mr. William Stirling, to the Falconer Memorial Fellowship, has been conferred for one year on Mr. Alexander Hodgkinson.

MR. P. L. SIMMONDS is now delivering at the London Institution, Finsbury Circus, the Travers Course for 1871-2, on Science and Commerce, illustrated by the raw materials of our manufactures, in two lectures, the first of which will be this evening, and the second on November 30th.

PROF. PARTRIDGE commenced his annual course of lectures on Anatomy to the pupils and Royal Academicians in the new theatre at Burlington House on Monday last week, and will continue the same every Monday evening up to December 11 inclusive, at eight o'clock.

AMONG the disastrous results of the recent fire at Chicago, one not referred to in the public papers was, we regret to learn from *Harper's Weekly*, the entire destruction of the building and collections of the Academy of Sciences of that city. This institution, first started by the energy of the late Mr. Robert Kennicott, and carried to its late condition of prosperity under the charge of Dr. William Stimpson, had already taken a front rank among the learned establishments of the country. Its publications embraced material of the utmost value, while its museum ranked at least as high as the fifth in the United States. Although believed to be fire-proof, the building, like others of the same character in Chicago, presented but little resistance to the flames, and everything within the walls was destroyed. The loss included, besides the collections in natural history of the Academy, a large number of marine invertebrates belonging to the Smithsonian Institution, which had been forwarded to Dr. Stimpson for investigation. The private cabinet of this gentleman, and a large mass of valuable manuscript belonging to him, embracing extended memoirs upon the mollusca, radiata, and crustacea of North America, with numerous illustrations, were entirely destroyed.

AFTER a seven years' tour of exploration in South America, Dr. A. Habel, a former resident of Hastings-on-the-Hudson, has returned to New York, where he is assiduously engaged in preparing the results of his labours for the press. Among the regions traversed by this gentleman may be mentioned the greater part of Central America, the Cordilleras of the Andes in Colombia, Ecuador, and Peru, and finally the Chincha Islands and the Galapagos. During this whole period Dr. Habel was diligently occupied in gathering information in regard to the natural and physical history of the countries mentioned, especially in the departments of ethnology, meteorology, and zoology. He has already made some communications on the subject of his travels to the Academy of Sciences at Paris, and other learned bodies, and we look forward to his detailed report with anticipations of

much interest. The Guano deposits of the Chinchas were thoroughly explored by the doctor, who found them to be of a much more complicated structure than has hitherto been supposed.

MR. MESTRE, the secretary of the Academy of Sciences of Havana, has lately offered on its behalf certain prizes for memoirs on subjects of medicine and natural history, indicating a gratifying condition of scientific activity in Cuba. Competition is open to persons of all nations, although the memoirs are to be written in the Spanish language. Among the prizes mentioned by Mr. Mestre is one of three hundred dollars, proposed by the president of the society, Dr. Gutierrez, for the best paper upon a certain beetle, which is very destructive to the sweet-potato. A full account of the animal and its habits is required, and the best method of protecting the plants against its ravages. The Zayas premium of one hundred dollars is offered for a paper upon the hygiene of children—to be written as an aid to mothers. Competition for these prizes is to close on the 1st of March, 1872.

THE Royal Geographical Society has again invited the following public schools to take part in the competition for its prize medals in 1872:—*English Schools*.—St. Peter's College, Radley, Abingdon; King Edward's School, Birmingham; Brighton College; Cathedral Grammar School, Chester; Cheltenham College; Clifton College; Dulwich College; Eton College; Haileybury College; Harrow; Hurstpierpoint; Liverpool College; Liverpool Institute; London,—Charter House; Christ's Hospital; City of London School; King's College School; St. Paul's; University College School; Westminster School; Royal Naval School, New Cross;—*Manchester School*; Marlborough College; University School, Nottingham; Repton; Rossall; Rugby; King's School, Sherborne; Shoreham; Shrewsbury; Stonyhurst College, Blackburn; Uppingham School; Wellington College; Winchester School. *Scotch Schools*.—Aberdeen Grammar School; Edinburgh Academy; Edinburgh High School; Glasgow High School. *Irish Schools*.—Royal Academical Institute, Belfast; Dungannon Royal School; Ennis College; Portora Royal School, Enniskillen; Foyle College, Londonderry; Rathfarham, St. Columba's College. Examinations will be held in both Physical and Political Geography, the special subjects for 1872 being as follows:—In Physical Geography; the Physical Geography of South America and the adjacent Islands, Trinidad, Galapagos, Falkland Islands, and Tierra del Fuego. In Political Geography; the Geography of the same districts.

THE Bussey Institution School of Agriculture and Horticulture, in connection with Harvard University, has been established in execution of the Trusts created by the will of Benjamin Bussey, to give thorough instruction in Agriculture, Useful and Ornamental Gardening, and Stock-Raising. In order to give the student a sound basis for a thorough knowledge of these Arts, the school supplies instruction in physical geography, meteorology, and the elements of geology, in chemistry and physics, in the elements of botany, zoology and entomology, in levelling and road-building, and in French and German. Connected with it are the names of such eminent professors as Asa Gray in botany, Whitney in geology, Shaler in zoology, and Trowbridge in physics.

A REPORT on the Physical Laboratory of the Massachusetts Institute of Technology, has been presented to Prof. J. D. Runkle, President of the Institute, by E. C. Pickering, Thayer Professor of Physics. The object designed by the establishment of the laboratory was to provide apparatus and other convenience for the performance of the more common lecture-room experiments, to supply a place where investigations of a high order can be carried on, and to train instructors in physics for the numerous colleges now springing up all over the Continent

of America. Particulars are given of a number of experiments of high order successfully carried on in the laboratory during the past year.

ENGLAND is beginning to acknowledge her forgotten scientific worthies. We learn that a public meeting was held last week at Birmingham, for the purpose of taking steps to establish a memorial to Dr. Priestley. It was resolved that the memorial should embrace three objects, viz., the purchase of a site, a scholarship, and a statue, so as to pay honour to Dr. Priestley both as a pioneer of science and as a champion of civil and religious liberty. A committee was appointed to carry the resolution into effect. It was stated that a sum of 3,000*l.* would be required, and several handsome subscriptions have been promised. The proposed site is that of the house at Fairhill, where Dr. Priestley resided for eleven years. The building was burnt down by rioters in 1791, after which he went to America.

THE Hartley Institution at Southampton has issued its Report for the year ending June 30, 1871. Although the managers of the Institution appear to have especially cultivated the training of engineering students for the Cooper's Hill College and elsewhere, the report refers with satisfaction to the increased number of students who have entered for general educational training as compared with former years.

THE Proceedings of the Bristol Naturalists' Society, vol. vi., part 1, for January to May 1871, contains the following papers:—The Natural History of the German People, by Dr. Beddoe; On the Origin of Species in Zymotic Diseases, by D. Davies; Personal Experiences in the Deep-sea Dredging Expedition in H.M.S. *Porcupine*, by W. L. Carpenter; On the Strata comprising the shores of Waterford Haven, with especial Reference to the Occurrence of Llandoil Fossils in that Locality, by Major T. Austin; On the Development of the Carboniferous System in the neighbourhood of Edinburgh, by E. W. Clappole; and On some Gravels in the Valley of the Thames in Berkshire, by E. W. Clappole. Valuable as these papers may be in themselves, it will be seen that not one of them has any special reference to the natural features of the neighbourhood of Bristol.

HERE is a grand opportunity for our young teachers of science; we give the trustees the benefit of the advertisement gratis:—“Grammar School of King Edward VI., Morpeth.—Wanted for the above school during the year 1872, a competent Master, to instruct the boys in modern languages (French and German indispensable). He will be required to attend at least forty days in each half year, and to teach not less than three hours each day. Salary, 50*l.* per annum. Travelling expenses at the rate of 10*l.* per annum will be allowed if the master does not reside in Morpeth. Also, a Master to teach elementary science (*botany, chemistry, and geology indispensable*). He will be required to attend twenty days in each half year, and devote three hours each day to teaching. Salary, 25*l.* per annum. Travelling expenses at the rate of 5*l.* per annum will be allowed as above. Also, a Master to teach practical drawing (to include mapping, planning, mechanical and architectural drawing). He will be required to attend twenty days in each half year, and devote three hours each day to teaching. Salary, 25*l.* per annum. Travelling expenses at the rate of 5*l.* per annum will be allowed as above. The trustees will not object to one master holding the two latter appointments. Applications, accompanied with testimonials, &c., to be sent to me on or before Friday, the 1st day of December next.—By order, BENJ. WOODMAN, Clerk to Trustees. Morpeth, 1st November, 1871.” Seriously, we had thought the days gone by when it was deemed possible to teach “botany, chemistry, and geology,” to say nothing of the other branches of “elementary science,” in sixty hours in each half year, and to remunerate the teacher who is competent to instruct in all these subjects, at the rate of 12*s.* 6*d.* per diem and 2*s.* 6*d.* extra for travelling expenses!

THE new edition of Gauss's "*Motus Corporum Coelestium*," which has just been published by Perthes, in Gotha, and which is designated as the seventh volume of Gauss's works, and is accompanied by a copy of the original vignette, might easily seem to be a part of the edition of Gauss's works, prepared by the Royal Society of Sciences in Göttingen. We are informed by that Society that the designation of this book as "Gauss's Works, vol. vii.," was chosen without their consent, and that it forms no part of the complete edition of Gauss's works, edited by the Royal Society, and now in the press.

WE are requested by Mr. R. A. Proctor to correct a slight error in the description of Mr. Brothers' negative of his star-chart given last week. The 8-inch negatives, like the 11-inch pictures, are copies of a chart containing upwards of 324,000 stars (not 50,000 only). Prof. Airy, at the last meeting of the Astronomical Society, remarked that the constellations in this chart are not conspicuous. They could not be so, without spoiling the chart; but the lithographic key-map practically removes the objection. The chart is a contribution to physical astronomy—not intended to aid the search for individual stars, though useful in the Observatory, as showing where the richer star-fields are.

MR. THOS. J. BOYD has reprinted his paper, "Educational Hospital Reform: The Scheme of the Edinburgh Merchant Company," presented to the Statistical Section at the recent meeting of the British Association.

A SERIES of "penny lectures for working men" in connection with the Museum of the Folkestone Natural History Society was commenced last week. The series is intended to illustrate the specimens in the museum—the subject of the first by the hon. secretary, Mr. Ulyett, being "Our Chalk Hills and their Fossils." If the experiment succeeds the lectures will be continued fortnightly during the winter months. Classes in botany and geology, also under the direction of the energetic secretary, were commenced on Wednesday, the 8th inst.

WE are glad to learn that the interesting series of popular science lectures, to which the charge of admission is only one penny, have been recommended this winter session in Manchester. The opening lecture was delivered by Prof. Huxley on "Yeast," before a large and attentive audience.

THE *Echo Agricole* complains of the neglect of instruction in science in France. "Why," says this journal, complaining of the importance attached in most schools to a semi-mythological teaching, "when an intelligence is just opening to the light, should it be led through the delusive labyrinths of the marvellous, instead of showing it the truth in all its splendour? Let the young intelligence be accustomed to the observation of natural phenomena, and it will be seen to develop itself normally, because to all the branches of activity which it is called upon to exercise it will bring the spirit of methodical order which it will have been obliged to employ in the study of nature. We therefore demand that the Minister of Public Instruction should introduce into our primary schools the elementary teaching of natural science applied to what children see daily in the country. M. Jules Simon has ordered that a geographical class should be held every fortnight in the colleges and lycées; now we would have the Minister complete this measure by requiring the students not only to mention the principal products of such and such a country, but, as regards France especially, to take account of the natural produce of the land, and to know what sort of soil these different products affect. This would be geography applied to agriculture. . . . Further, we would require that all sciences relating to agriculture taught in the lycées and colleges should be followed by practical application to the soil, such experiments to form the basis of special examinations."

A DISCOVERY has been made by several farmers on the Loddon River in South Australia, that kangaroo rats are good thistle eradicators. "It has been found," says the *Bendigo Independent*, "that these animals dig down under the thistles, and eat the roots of the plants, which thus necessarily die. One farmer has issued orders that no kangaroo rats are to be killed on his land, in consequence of their having been of much service to him in destroying the obnoxious thistles."

At a meeting of the Philosophical Society of Christchurch, New Zealand, in August last, the President, Dr. Haast, made a few observations on some moa eggs recently received from the Colonial Museum, in comparison with those of living birds. The various models of eggs were displayed on the table. The President said that the first egg to which he would desire to draw their attention was one the pieces of which had been discovered by the Hon. Walter Mantell, and by him reunited after much labour. The original egg, from which a model had been taken by Dr. Hector, was in the British Museum. The second model was that of the largest egg found. It had been discovered in the Kaikoras Peninsula, between the legs of a human skeleton, which had been buried in a sitting position, and, from the fact of it having been so found, he argued that the moa was of great antiquity, as there was no mention in the very earliest Maori traditions of such a mode of burial being adopted. The egg was afterwards exhibited at the Otago Exhibition, and the model had been made by Dr. Hector from measurements taken by him. The third and last model was that of a small egg now in the Colonial Museum, which had been found in Otago, and which had in it the bones of a moa chick.

On the 17th of September the installation of the Academy of Natural Science took place at Bogota, in Columbia or New Granada, with much ceremony. As yet not much can be expected from it, but it is another sign of the progress taking place in the country. The orator gratefully commemorated what had been done for Columbia by Humboldt, Boussingault, and Acosta in geology, and by Mutis and Caldes in botany.

THE first meeting of the Eastbourne Natural History Society for the present season was held on Friday, October 20. A paper "On the species of Hepaticæ found in the Eastbourne District" was read by Mr. F. C. S. Roper, F.L.S., containing notes on the structure and development of the group, with a list of the species (fifteen in number) occurring in the neighbourhood. It was followed by a paper "On the Bones of Red Deer, &c., found in Eastbourne," by Mr. S. Eveshed. We are glad to observe that active local work is a prominent feature of this young society.

THE Whitechapel Foundation School Literary and Scientific Society held its first annual public meeting last week in the School-room, Leman Street. The Chairman, Mr. Edmund Hay Currie, member of the London School Board, having briefly referred to the importance of the work, and to the dissemination of scientific knowledge by the society's agency, called upon the hon. secretary to read the report; from this we gleaned that the association had made good progress during its first year of existence, and that the interest in the undertaking was rapidly increasing. Twenty-six lectures had been delivered, amongst the principal subjects were "Oxygen and Hydrogen," by Mr. Joseph Loane, M.R.C.S., L.S.A., &c., &c., "Blood and its Constituents," and "Respiration, with its Mechanism," by Mr. H. A. A. Nicholls, of St. Bartholomew Hospital; "The Solar System," "Heat," "Coal and its products," "Electricity," "Chemical affinity," "Water," &c., &c. The evening's proceedings were brought to a termination with a lecture on "Light," illustrated by experiments, by the President, Mr. Charles Judd. We are glad to find that this society has received considerable recognition from gentlemen interested in science and in education generally.

COLDING ON THE LAWS OF CURRENTS
IN ORDINARY CONDUITS AND IN THE
SEA

[I SEND to NATURE for translation the abstract (in French) appended, according to a most excellent custom, to Colding's great paper in the Copenhagen Transactions. The subject is one of especial interest at the present time, though, of course, everything written by such a man is deserving of careful attention. Those in particular who met the genial Dane at the British Association will be glad to have in a compact form his views on a question which has given rise to much discussion, and which is of very great practical importance.—P. G. TAIT]

I PRESENTED in 1863 to the Scientific Society, and some months later to the Congress of Scandinavian Naturalists at Stockholm, a short exposition of my researches on the motion of fluid bodies, on which I had been occupied for several years, and the results of which appeared to me worthy of being submitted to the Society.

The characteristic of this work is that it does not suppose, like previous works of the same kind, that all the parts of a current are endowed with the same rapidity; for it owes, in fact, its existence to my conviction that this mode of looking at the subject can only lead in exceptional cases to exact results. My researches are based on the different motions assumed by the liquid threads or elements of the currents, and are supported by the well-known fact that any body, and consequently any portion of a fluid, can only move with a constant rapidity when the accelerating force is equal to the resistance.

In the case of a fluid flowing by virtue of its own weight over a plane surface which opposes a resistance to the motion of the water, it was easy to determine how this motion varies with the depth, when the rapidity of the current is constant in all its parts; and, by pursuing this train of thought, I was led to the law of the variation of the rapidity with the depth, when the current moves in a cylindrical conduit with circular section, completely filled with the liquid. These researches are of greater interest from the circumstance that the laws at which I have in this manner arrived from theoretical considerations, are confirmed by the experiments which have recently been carried out in France by Capt. Boileau and Inspector-General Darcy. These laws of the motion of water may be expressed by the formula

$$(V - v)^2 = K_0^2 \frac{h}{\lambda} x^3;$$

where V is the rapidity of the first elements of the current, the motion of which is the most rapid, v the rapidity at the depth x , $\frac{h}{\lambda}$ the fall per foot of the water, and K_0^2 a magnitude which depends entirely on the nature and dimensions of the conduit, on the depth of the current, &c. The theory shows besides that the laws of the motion of water on a level surface are included in the general law of the motion of water on a cylindrical surface, when the radius of the cylinder is supposed infinite.

Darcy, who has experimentally established the formula given above for cylindrical conduits, endeavoured, at the same time, to determine K_0^2 by means of certain experiments performed with four different kinds of pipes, and found that K_0^2 was inversely proportional to the square of the radius of the conduit. It resulted, according to the theory, that, for level conduits, K_0^2 should be in the same manner in an inverse ratio to the square of the depth of the current. But two series of experiments performed by Boileau with level conduits led, on the contrary, to the supposition that K_0^2 was inversely proportional simply to the depth of the current. There was thus a want of agreement between the results of the two experiments, and the point was to discover which of these two hypotheses was correct. Several circumstances leading me to believe that Darcy's theory could not be exact, I took as my starting point the experiments of Boileau, and considered K_0^2 as inversely proportional to the depth of the current, which I did with the less scruple since this hypothesis agreed almost as well with Darcy's experiments as with his own. I pursued, therefore, my researches on this basis, and, after many difficulties, arrived at results which, on the whole, were so entirely in accordance with experiments that I could not suppose the possibility of Boileau's hypothesis being inexact. It was only afterwards, when I approached the study of marine currents, that new difficulties constantly arose, which I endeavoured at first to overcome, but which became day by day more insur-

mountable, until at last there was nothing left but to doubt the correctness of my calculations, since they led to results which were in obvious contradiction to facts.

The theory then was shown to be inexact; but since in so large a number of cases it was evidently in agreement with experiment, I attempted by a variety of means to discover the error which I must have committed; still all my attempts were unattended with result, and I was on the point of abandoning the resolution of the problem to which I had already devoted so much time, when the idea struck me of examining what would happen if I rejected Boileau's determination of K_0^2 , and adopted Darcy's hypothesis, although it still appeared to me impossible; when I found, with as much delight as surprise, that it removed not only the great difficulties which I had up to that time encountered, but also all the contradictions which had occurred to me as an inevitable consequence of that hypothesis, and from that moment the results of the calculations showed themselves to be entirely in the most perfect accordance with what exists in nature.

The circumstance that the experiments of Darcy are almost as satisfactory whether $\frac{1}{K_0^2}$ is supposed to be proportional to the

first or to the second power of the depth of the currents, made me think that the reality would be still more nearly approached by expressing this magnitude by a binomial of the first and second degree, and this was completely confirmed by facts. In determining the constants of the binomial according to the results of Darcy's experiments, I found the law of the motion of the water in cylindrical pipes with a radius R , with a coefficient of resistance m , and a rapidity v_0 at the surface of the conduit, may be represented by the formula

$$V - v = 6.8 \sqrt{m} \times v_0 \times \left(\frac{x}{R}\right)^{\frac{3}{2}} \sqrt{\frac{117.7 R}{62.5 + 117.7 R}}$$

V being the rapidity next the axis, to which corresponds $x = 0$. This formula may be applied equally to the movement of water in level conduits, if by R is designated the depth of the current;

only the coefficient then becomes $\frac{6.8}{\sqrt{2}} = 4.8$, instead of 6.8.

This formula shows, among other things, that the ratio $\frac{v}{V}$

which corresponds to any point in a given conduit entirely filled by the current, is entirely independent of the rapidity of the current, a fact which Darcy's experiments confirm in a remarkable manner. This relation furnishes us besides with the means of determining the value of the coefficient of resistance m for different kinds of pipes which were employed by Darcy, and it is thus found that for

Old pipes	m = from 0.0120 to 0.0080
New pipes	m = from 0.0050 to 0.0033
New varnished pipes.	m = from 0.0033 to 0.0025

values which are altogether independent of the diameter of the conduit. For level wooden conduits, it is found, according to the experiments of Boileau, that $m = 0.0160$ to 0.0090, while the resistance of the air, according to the same author, corresponds to $m = 0.0003$ to 0.0002.

Inspector-General Darcy has unfortunately died, but the researches on currents which he commenced were continued by the French engineer Bazin, who published in 1865 a great work on the results of a considerable number of experiments carried on with conduits of very different kinds.

However interesting otherwise these researches may be, they do not display either the powers of observation or the grandeur of conception which distinguish the works of Darcy. Among those experiments which are of the greatest interest, there are some begun by Darcy and finished by Bazin, such as researches into the motion of water in rectangular conduits, where the rapidity is determined in 45 points symmetrically distributed. The result

for these, as for circular conduits, is that the ratio $\frac{v}{V}$ is independent of the absolute rapidity of the current, and if the results of experiment on the motion of water in level conduits are compared with those given by the theoretic formulae, it will be found that these last agree so completely with experiment, that the difference between the calculated and observed rapidities, in each of the 45 points mentioned above, falls within the limit of errors of observation. This agreement is especially remarkable in the case of the conduit which Darcy employed in 1857 for the carrying out

of his researches. In 1859 Bazin undertook similar experiments with a small rectangular conduit; but he did not make so great a number of experiments, and his errors of observation are larger than those of Darcy. In determining the coefficients of resistance of these conduits, it was found that for those of Darcy $m = .0104$, while for those of Bazin it rose to 0.0180 .

Bazin performed a considerable number of experiments on the motion of water in open conduits, and thought himself compelled to admit that the laws of this motion are essentially different from those which relate to perfectly full conduits; but he is certainly in error.

The results of a considerable number of ancient measures of currents are in existence, which Bruning undertook, towards the close of last century, in different rivers—namely, the Rhine, Waal, &c. They were performed with much care; but, as might be foreseen, are nevertheless very defective. They deserve, however, to attract attention, partly because the rapidity was determined, for every section of the current, at distances of six inches from the surface to the bottom, in a series of perpendiculars, the imperfections which the measurement of the rapidity presents losing thus much of their importance; partly and especially because the currents examined by Bruning were of a depth which reached 23 feet. In applying this theory to these currents, and especially in determining the constants of the formulæ with the aid of Bruning's measurements, it was found that the observed and calculated rapidities are for all depths as accordant as could be desired; and this agreement furnishes a new proof of the exactness of the theory. The coefficient of resistance m , calculated according to Bruning's measurements, varies between 0.0250 and 0.0080 , with a mean of 0.0160 ; and as the resistance at the depth of these currents must doubtless approach that which a marine current experiences in flowing over a mass of water placed beneath it, and which does not participate in the motion, I have a right to believe that the extreme value $m = 0.0250$ corresponds nearly to the resistance which currents meet with when flowing freely in the sea.

After having in this manner assured myself that the preceding theory agrees with experiment wherever it has been tried, I endeavoured to determine the laws of the motion of water in currents of variable rapidity. In considering the simplest case of this kind, that, namely, in which the conduit is a level surface (I had already treated this case by the old theory), it was found that the laws of currents, according to the new theory, are entirely in agreement with the facts observed in nature; and consequently this theory may be regarded as giving the explanation of all permanent currents.

Having thus shown that this theory of the movement of fluid bodies accounts satisfactorily for all the phenomena, I shall now, from this as a standpoint, give a review of my recent researches upon ocean currents. The currents which more particularly demand our attention here are those of the North Atlantic, especially the Gulf Stream and the Polar Currents.

The Gulf Stream issues, as we know, from the Gulf of Mexico, but it is possible to follow its course across the Caribbean Sea, where, passing between the Antilles, it arrives from the Atlantic, and afterwards flows to the north-west at the rate of $\frac{1}{4}$ mile an hour until it enters the Gulf of Mexico. From this Gulf the Gulf Stream takes an easterly course towards the Bahamas along the north coast of Cuba; but, after rounding Florida, it bends northwards, and passes between the latter and the Bahamas, in the channel which separates Florida Cape from the Isles of Bemini; here the current has a speed of 1 mile per hour, a breadth of 8 miles, and a depth of 250 fathoms. From the channel of Bemini the Gulf Stream proceeds directly northwards at a rate which decreases gradually from 63 feet per second at Bemini to 4 feet at St Augustine; the distance between these two points being about 70 miles, during which the breadth of the current increases from 8 miles to $11\frac{1}{2}$. From St. Augustine to the Bay of New York the Gulf Stream takes a north-easterly course, parallel with the land, and continuous with a cold current which flows from the north to the south between the stream and the American coast. In this part of its course it continues to increase in breadth from 11 miles at St. Augustine to $31\frac{1}{2}$ at New York; meanwhile its speed decreases from 4 feet to $2\frac{1}{2}$ feet per second. The depth of the sea along the course of the current is many hundred fathoms, and the distance between St. Augustine and New York is 180 miles. On quitting the Bay of New York, the Gulf Stream takes an E.N.E. direction to the south of Newfoundland, skirting the cold current, which goes down to south-west as far as New York, following the east coast of Newfound-

land. By the time the Gulf Stream, after a course of 200 miles, reaches the south of Newfoundland, it has attained a breadth of about 80 miles, while its speed is only 2 feet per second; but the current continues to run in the same direction towards Europe for other 300 miles, with a speed which is from 2 feet to 0.6 feet, and a breadth increasing from 80 up to 200 miles. The Gulf Stream, when it has attained a distance of 750 miles from Bemini, separates into two branches, the one proceeding southwards towards the coast of Africa, at a speed of 0.6 feet per second, the other taking a northerly course towards Iceland, along the shores of the British Islands, and running about 200 miles, at a rate which decreases from 0.6 to 0.3 feet per second, the breadth of the current meanwhile increasing from 100 to 105 miles. When the stream reaches the neighbourhood of Iceland, it sends off a branch which skirts the south coast of that island, afterwards taking a direction north-west towards the Polar current of the east coast of Greenland, which it seems partly to follow in its march southwards. As to the main stream, it inclines to the east after passing the extreme north of Scotland, and then runs to the north-east, along the west coast of Norway, until it ends its wanderings in the Icy Sea.

As to the Polar Current we feel authorised to mention the following statements:—From the region of the Icy Sea, the most northerly of which we have any knowledge, from the neighbourhood of Spitzbergen about the 80th degree of N. latitude, there descends to the south-west a great polar current loaded with floating ice. It reaches the coast of Greenland at about 70° N. latitude, and follows it as far as Cape Farewell; its breadth being nearly 40 miles and its speed $\frac{1}{4}$ of a foot per second. After passing Cape Farewell, it curves round to northward and follows the west coast of Greenland for some distance into Davis Strait. After having run for a few degrees in this direction it bends to the south-west, towards the coast of Labrador, along the whole length of which it runs, then proceeding to the south-east, enlarged by the polar current which comes from Baffin's Bay. On quitting Labrador, where its speed is $\frac{2}{5}$ of a foot per second, and its breadth 50 miles, the polar current on rounding the east coast of Newfoundland makes for the Gulf Stream, and, after doubling Cape Race, sends a branch to the south-west between the Gulf Stream and the American coast, which branch can be traced as far as Florida. As to the part of the polar current which does not take this route, it is generally admitted that it flows underneath the Gulf Stream on the east of Newfoundland, and that it runs uninterruptedly to the south-east, towards the African coast, where the waters of the ocean are of a temperature comparatively low.

In order to explain the causes of these immense ocean currents by the aid of the laws of the movement of water in ordinary conduits, it is necessary first of all to know the forces which produce and maintain the movement of these currents. Captain Maury, who has made a special study of this question, has given it as his opinion that these ocean currents are due to the differences caused by the changes of temperature and of saltness in the specific gravity of the water of the sea. In order to make this theory more easy of comprehension, Maury imagines a globe like the earth covered over the whole of its surface with a sea 200 fathoms in depth, the water throughout being of the same density; at the same time he supposes the surrounding circumstances to be the same at all points, and that there being neither evaporation nor precipitation, there can of course be neither winds nor currents upon the imaginary globe. He next supposed the water contained between the tropics suddenly transformed into oil to a depth of 100 fathoms. From this moment the equilibrium is destroyed, and there results a general system of currents and counter-currents; for the oil, being lighter than the water, will rush along the surface towards the poles, while the water of these regions makes for the equator in the shape of a submarine current. As the oil reaches the polar sea, it is supposed to be transformed into water, which returns to the equator, where it is changed anew into oil that again rises to the surface and again makes its way to the poles, and so on. If then this globe turns, like the earth, on its axis once in the twenty-four hours from west to east, each particle of oil, according to Maury, will proceed towards the pole in a spiral course with a speed towards the east always increasing; on reaching the pole it will turn at a rate equal to that at which the earth revolves at the equator, viz., 225 miles an hour. But, says Maury, when the oil has been changed into water, it will return towards the equator describing a curve in a westerly direction. If the sea in question should be bounded by land, as is the case on the surface of the earth, the uniformity of

these currents will be broken up by different local circumstances; and the speed of the currents will vary at various places, but there will always be a system of equatorial and polar currents. Is it not admissible then to suppose, asks Maury, that the cold waters coming from the north and the warm waters issuing from the Gulf of Mexico and made lighter by the heat of the tropics, will act relatively to each other in the same way as the water and the oil in the preceding example?

The Gulf Stream was at one time regarded as a branch of the Mississippi; but this notion must be abandoned since it has been proved that the volume of the Gulf Stream is many thousand times greater than that of the river, and that its water is salt, while the water of the Mississippi is fresh. Next, Benjamin Franklin's idea was generally adopted, viz., that the trade-winds drive the waters before them into the Caribbean Sea, whence they issue more slowly in forming the Gulf Stream. Maury, however, refuses to accept this explanation; he admits that the trade-winds may increase the speed of the stream in the strait of Florida, but he maintains that it is impossible for these winds to give such an impetus to the Gulf Stream as would make it traverse the whole of the Atlantic as a markedly distinct current. He caps his objections to the theory of Franklin by remarking, that as surely as a river flows along its bed only under the influence of gravity, so the course of the Gulf Stream in the midst of the ocean necessitates the existence of a never-ceasing moving force; in short, he says, if gravity did not exist, the waters of the Mississippi would never leave their source, and, were it not for a difference of specific weight, those of the Gulf Stream would remain for ever in the tropical regions of the Atlantic. But as Maury disputes the correctness of Franklin's statement, viz., that the surface of the sea is above the normal level in the Gulf of Mexico, and that the water tends by virtue of its weight to rush towards the north, and as observation has proved that along the western edge of the Gulf Stream there flows a current of those cold waters which descend southwards as far as Florida Strait, he can no longer maintain his first opinion as to the cause of the Gulf Stream. He is forced to resign the hypothesis that the water of the Gulf Stream, on account of its greater degree of saltiness, has a specific gravity greater than the water of the polar seas, to which it flows in virtue of its great density, causing a current in a direction contrary to the lighter waters of these colder regions. But from the moment that Maury supposes that the ocean currents have their origin at the time when the water of the tropics is lighter, and that of the Gulf Stream heavier than the water of the Polar seas, his point of view becomes uncertain and difficult to sustain; and he fails all the more signally in presenting the question of the currents in its true light, from the fact that at that time there existed no exact method of obtaining the specific gravity of the water of the ocean, the degree of saltiness of the different seas being then unknown.

(To be continued.)

PHYSIOLOGY FOR WOMEN *

BY Physiology we should understand a knowledge of the functions of the human body, and of the laws which regulate and maintain its various actions. The physiology of plants and of the lower tribes of animals (Botany and Zoology) are described by two other Professors in the University, and there will be little enough time for me to condense and give an account of what is now known of the subject, even as I have limited it. Whatever useful information, however, can throw light on human physiology, derived from every collateral science, will be made use of to assist inquiry. After some preliminary lectures on the histology, chemistry, the physical and vital properties of the tissues, I shall more especially dwell on the two great functions of nutrition and innervation. The former involves an acquaintance with what constitutes a proper food for man—how it is prepared by mastication, insalivation, digestion, chymification, sanguification, and respiration, to form the blood; how out of this blood the tissues are formed; and how, after these have fulfilled their proper uses, they are separated from the body in the act of excretion. The latter comprehends a description of the functions of mind, including the mental acts, sensibility, sensation, volition, and the varied kinds

of motion; of the functions of the nerves; of the special senses, such as smell, taste, touch, sight, hearing, and the muscular sense of voice and speech; and lastly, of sleep, dreams, somnambulism, catalepsy, trance, witchcraft, animal magnetism, &c. &c. Of the subjects included under these heads it is impossible to overrate the importance in reference to their relation to the health and happiness of man, his physical and moral welfare, his social relations, his national resources, and the prosperity of his race. I have long formed the opinion that physiology, besides being essential to the medical student, should be introduced as an elementary subject of education in all our schools—should be taught to all classes of society. It is an ascertained fact that 100,000 individuals perish annually in this country from causes which are easily preventable, and that a large amount of misery is caused by an ignorance of the laws of health. The clergy should especially study it—first, with a view of diminishing the difference in thought existing between literary and scientific men; and, secondly, because their influence on the people from the pulpit, and as parish ministers, is so important. All other professions and trades, however, might beneficially study physiology, especially newspaper editors and reporters, who diffuse a knowledge of useful things among the public; and architects, who have not yet learnt to build dwelling-houses and public halls properly ventilated. But women, in all classes and degrees of society, have more to do with the preservation and duration of human life even than men. It has been argued that, inasmuch as even the brutes know instinctively how to take care of their young, so must women be able to do the same. But the human infant is the most helpless of creatures, and nothing is more lamentable than to witness the anxieties and agony of the young mother as to how she should manage her first-born. In no system of education are women taught the structure and requirements of the offspring which will be committed to their charge; and certainly no error can be greater than to suppose that the senses and instincts are sufficient for teaching man as to his physical, vital, and intellectual wants. The enormous loss of life among infants has struck all who have paid attention to the subject, and there can be no question that this is mainly owing to neglect, want of proper food or clothing, of cleanliness, of fresh air, and other preventable causes. Dr. Lankester tells us, when ably writing on this topic, that, as coroner for Central Middlesex, he holds one hundred inquests annually on children found suffocated in bed by the side of their mothers, and he calculates that in this way 3,000 infants are destroyed in Great Britain annually alone, attributable in nine cases out of ten to the gross ignorance of those mothers of the laws which govern the life of the child.* But women are the wives and regulators of the domestic households. They also constitute the great mass of our domestic servants. On them depends the proper ventilation of the rooms, and especially the sleeping rooms, in which all mankind on an average spend one-third of their lives. Children are too often shut up all day in crowded nurseries, and when ill, are subjected to numerous absurd remedies before medical assistance is sent for. Their clothing is often useless or neglected, the dictation of fashion rather than of comfort and warmth being too frequently attended to. The cleanliness of the house also depends on women, and the removal of organic matter from furniture and linen, the decomposition of which is so productive of disease. Further, the proper choice and preparation of food is entrusted to them,—all these are physiological subjects, the ignorance of which is constantly leading to the greatest unhappiness, ill health, and death. Among the working classes it is too frequently the improvidence and ignorance of the women which lead to the intemperance and brutality of the men, from which originate half the vice and crime known to our police offices and courts of justice. Additional arguments for the study of physiology by women may be derived from the consideration of—(1) the effects of fashionable clothing—the tight lacing, naked shoulders, thin shoes, high-heeled boots—often subversive of health; (2) the great objects of marriage—the production of healthy offspring—and all the foresight, care, and provision required, but too often neglected through ignorance, to the danger both of mother and child; (3) the proper employment of women, which should be regulated with regard to their conformation and constitutions; and (4) nursing the sick, which is one of the most holy occupations of women, and which would be much more intelligently done if

* Abstract of the Opening Lecture of the Ladies' Course of Physiology, delivered in the University of Edinburgh, Nov. 2, by Prof. Bennett.

* See his excellent pamphlet, "What shall we Teach; or Physiology in Schools." London: Groombridge & Sons, 1870.

they possessed physiological knowledge. Doubtless those who regard this study as too difficult and technical for young men, will deary it also for women; yet it so happens that for them nothing is so truly interesting as this science. The examination-papers of school-girls of the Ewart Institution, Newton-Stewart, contain an amount of information in physiology perfectly astonishing. Seldom have medical students given better answers. And yet it has been argued that physiology was far too difficult and technical a subject to be studied even by the students in Arts of our University. Hence women in all ranks of society should have physiology taught to them. It should be an essential subject in their primary, secondary, and higher schools. So strong are my convictions on this subject, that I esteem it a special duty to lecture on physiology to women, and whenever I have done so, have found them most attentive and interested in the subject, possessing indeed a peculiar aptitude for the study, and an instinctive feeling, whether as servants or mistresses, wives or mothers, that that science contains for them, more than any other, the elements of real and useful knowledge.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, November 8.—Joseph Prestwich, F.R.S., president, in the chair. Mr. Henry Hicks was elected a Fellow, Dr. Franz Ritter von Hauer, of Vienna, a Foreign Member; and M. Henri Coquand, of Marseilles, a Foreign Correspondent of the Society. The following communications were read:—1. A letter from the Embassy at Copenhagen, transmitted by Earl Granville, mentioning that a Swedish scientific expedition, just returned from the coast of Greenland, had brought home a number of masses of meteoric iron found there upon the surface of the ground. These masses varied greatly in size; the largest was said to weigh 25 tons. Mr. David Forbes, having recently returned from Stockholm, where he had the opportunity of examining these remarkable masses of native iron, took the opportunity of stating that they had been first discovered last year by the Swedish Arctic expedition, which brought back several blocks of considerable size, which had been found on the coast of Greenland. The expedition of this year, however, has just succeeded in bringing back more than twenty additional specimens, amongst which were two of enormous size. The largest, weighing more than 49,000 Swedish pounds, or about 21 tons English, with a maximum sectional area of about 42 square feet, is now placed in the hall of the Royal Academy of Stockholm; whilst, as a compliment to Denmark, on whose territory they were found, the second largest, weighing 20,000 lbs., or about 9 tons, has been presented to the Museum of Copenhagen. Several of these specimens have been submitted to chemical analysis, which proved them to contain nearly 5 per cent. of nickel, with from 1 to 2 per cent. of carbon, and to be quite identical, in chemical composition, with many aerolites of known meteoric origin. When polished and etched by acids, the surface of these masses of metallic iron shows the peculiar figures or markings usually considered characteristic of native iron of meteoric origin. The masses themselves were discovered lying loose on the shore, but immediately resting upon basaltic rocks (probably of Miocene age), in which they appeared to have been originally imbedded; and not only have fragments of similar iron been met with in the basalt, but the basalt itself, upon being examined, is found to contain minute particles of metallic iron, identical in chemical composition with that of the large masses themselves, whilst some of the masses of native iron are observed to enclose fragments of the basalt. As the chemical composition and mineralogical character of these masses of native iron are quite different from those of any iron of terrestrial origin, and altogether identical with those of undoubted meteoric iron, Prof. Nordenskjöld regards them as aerolites, and accounts for their occurrence in the basalt by supposing that they proceeded from a shower of meteorites which had fallen down and buried themselves in the molten basalt during an eruption in the Miocene period. Notwithstanding that these masses of metallic iron were found lying on the shore between the ebb and flow of tide, it has been found, upon their removal to Stockholm, that they perish with extraordinary rapidity, breaking up rapidly and falling to a fine powder. Attempts to preserve them by covering them with a coat of varnish have as yet proved unsuccessful; and it is actually proposed to preserve them from destruction by keeping them in a tank of

alcohol. Mr. Maskelyne stated that the British Museum already possessed a specimen of this native iron, and accounted for its rapid destruction on exposure by the absorption of chlorine from terrestrial sources, which brought about the formation of ferrous chloride. This was particularly marked in the case of the great Melbourne meteorite in the British Museum; he had succeeded in protecting this, as well as the Greenland specimen, by coating them externally, after previously heating them gently, with a varnish made of shellac dissolved in nearly absolute alcohol. He considered it probable that a meteoric mass falling with immense velocity might so shatter itself as to cause some of its fragments to enclose fragments of basalt, and even to impregnate the neighbouring mass of basalt with minute particles of the metallic iron; but he considered the question of meteoric origin could only be decided by examining the same mass of basalt at some greater distance from the stones themselves, so as to prove whether the presence of such metallic iron was actually characteristic of the entire mass of the rock. Prof. Ramsay referred to the general nature of meteorites and to their mineral relationship to the planetary bodies, and remarked that, supposing the earth to have in part an elementary metallic core, eruptive igneous matter might occasionally bring native iron to the surface. Mr. Daintree mentioned that he had been present at the exhumation of the Melbourne meteorite, and that at that time there was little or no trace of any exudation of ferrous chloride, the external crust on the meteorite being not above $\frac{1}{2}$ inch in thickness. 2. "On the Geology of the Diamond-fields of South Africa," by Dr. J. Shaw, of Colesberg. Communicated by Dr. Hooker, F.R.S. The author described the general structure of the region in which diamonds have been found. He considered that the diamonds originally belonged to some metamorphic rock, probably a talcose slate, which occupied the heights during a late period of the "trappean upheaval," to which he ascribed the origin of the chief physical features of the country. This upheaval was followed by a period of lakes, the traces of which still exist in the so-called "pans" of the region; the Vaal river probably connected a chain of these lakes; and it is in the valley of the Vaal and the soil of the dried up "pans" that the diamonds are found. The author referred also to the frequent disturbance and removal of the diamantiferous gravels by the floods which prevail in these districts after thunder-storms. 3. "On the Diamond-gravels of the Vaal River, South Africa," by Mr. G. W. Stow, of Queenstown, Cape Colony. Communicated by Prof. T. Rupert Jones. The author described the general geographical features of the country in which diamonds have been found, from Mamusa on the south-west to the headwaters of the Vaal and Orange Rivers. He then indicated the mode of occurrence of the diamonds in the gravels, gravelly clays, and boulder-drifts of the Vaal Valley, near Pniel, including Hebron, Diamondia, Cawood's Hope, Gong Gong, Klip Drift, Du Toit's Pan, and other diggings. By means of sections he showed the successive deepening of the Vaal Valley and the gradual accumulation of gravel-banks and terraces, and illustrated the enormous catchment area of the river-system, with indications of the geological structure of the mountains at the headwaters. The specimens sent by Mr. Stow, as interpreted by Prof. T. R. Jones, showed that both igneous and metamorphic rocks had supplied the material of these gravels. The author concluded that a large proportion of these materials have travelled long distances, probably from the Draakensberg range; but whether the original matrix of the diamonds is to be found in the distant mountains or at intermediate spots in the valleys, the worn and crushed condition of some of the diamonds indicates long travel, probably with ice-action. Polished rock-surfaces and striated boulders, seen by Mr. Gilliland, were quoted in corroboration of this view. Mr. Woodward mentioned that Mr. Griesbach and M. Hübner had been over the country described in these papers, and had communicated a map of it to Petermann's Journal. Mr. Griesbach stated that the rock described as metamorphic in the paper was by M. Hübner regarded as melaphyre, and that in some parts of the Vaal Valley the beds of the Karoo formation might be seen *in situ*. He disputed the possibility of any of the gravels being of glacial origin. He was convinced that there were no metamorphic rocks on the western side of the Draakensberg; those regarded as such probably belonged to the Karoo formation. Prof. Tennant commented on the large size of the diamonds from the Cape, of which he had within the last few months seen at least 10,000, many of them from 30 to 90 carats each. Some broken specimens must, when perfect, have been as large as the Koh-i-Noor. Mr. Tobin corroborated the infor-

material given by Mr. Stow, and stated that the source of the Vast was in sandstone, and that it was not until it had traversed some distance that agates, peridot, and spinel were met with. The large diamonds, in his view, occurred principally in old high-level gravels, at a considerable elevation above the river, which had much deepened its valley since the time of their deposit. At Du Toit's Pan, however, none of the diamonds, nor indeed any of the other stones, showed any signs of wear; and he considered that at that spot was one of the centres at which diamonds had been found in their original matrix. Mr. Daintree stated that in Australia there were agate-bearing beds of amygdaloid greenstone similar to those in South Africa, and that he had called attention to their existence in the neighbourhood of the Burnett River, where since then a diamond of the value of 80*l.* had been discovered. Mr. Maskelyne commented on the dissimilarity of the minerals found in the diamond-bearing beds of Brazil from those of Du Toit's Pan or of South Africa generally. He thought that possibly the minerals described as peridot and spinel might be bronzite and garnet, which, however, came from igneous rocks; and the remarkable fact was that with them occurred unrolled natrolite and diamonds in an equally unrolled condition, which was suggestive of their having been due to a common origin. Mr. Ward gave an account of an examination of some of the rock from Du Toit's Pan, with a view of discovering microscopic diamonds, none of which, however, had been found. Prof. Rupert Jones had been equally unsuccessful in the search for minute diamonds, both in sand from Du Toit's and in the ochreous gravel from Klip drift. He pointed out the waterworn condition of the agates from Du Toit's Pan, which showed aqueous action, though there were also several other minerals present in a perfectly fresh and unrolled condition. He thought a careful examination of the constituent parts of the gravel might ultimately throw light on their origin. That fluvial action was sufficient to account for their presence had already been shown by Dr. Rubidge and others, who had treated of the grand plateaux and denudations of the district under notice.

Royal Geographical Society, November 13.—Major-General Sir H. C. Rawlinson, K.C.B., president, in the chair. The president, on opening the session, delivered an address, in which, after paying an eloquent tribute to the worth of the late president, Sir Roderick Murchison, and expressing his sense of the loss which the Society had sustained in his death, he reviewed the progress of geography since the last meeting of the previous Session. He congratulated the Fellows on being again permitted to meet in the handsome and commodious hall of the London University; and stated that the Council felt that the Senate of that body, in granting the use of the hall, conferred an obligation not only on the Society but on the public at large, whose instruction and education in geography formed the especial objects of their study. He also announced that the Society had, during the recess, taken up its permanent quarters in Savile Row, where it was now located on its own freehold estate. In Physical Geography the important subject of Oceanic Circulation, and Dr. Carpenter's researches thereupon, was prominently noticed; and he stated that Dr. Carpenter, during his Mediterranean voyage of the past summer, had met the objections of his critics in so far as related to the under-current outwards at the Straits of Gibraltar by experimentally proving that such a current really does exist. In Arctic exploration the recent German expeditions were noticed, particularly the voyage of Messrs. Payer and Weyprecht, who, last summer, had found an open sea, in lat. 70°, between Spitzbergen and Nova Zembla. In Central Asia and Eastern Persia much accurate information had recently been obtained by English travellers and surveyors; and in Syria their medallist, Captain Burton, had recently, in company with Mr. Drake, examined the Anti-Libanus and the little-known district east of Damascus,—subjects on which this indefatigable traveller would read papers at a subsequent meeting. An excellent descriptive paper had been received from the well-known and able traveller Captain Blakiston, on the subject of the island of Yezo, the circuit of which he had recently explored in the capacity of an official of the Japanese Government. No direct news had been recently received either from Dr. Livingstone or Sir Samuel Baker; but authentic intelligence of Livingstone could not be much further delayed, as an able and adventurous American gentleman, Mr. Stanley, left Zanzibar for the shores of Lake Tanganyika in February last, taking with him "Bombay," one of Speke and Grant's "faithfuls," as guide. He (the president) added that if Mr. Stanley succeeded in restoring Livingstone to

us, or in assisting him to solve the great problem of the upper drainage into the Nile or Congo, he would be welcomed by the Society as heartily and warmly as if he were acting under their own immediate auspices.—A paper was then read "On the Exploration of the Limpopo River," by Captain Frederic Elton. This remarkable journey was performed between July 5 and August 8, 1870, the author starting from the Tati gold-fields and proceeding by an easterly route to the junction of the Tuli River with the Limpopo, and thence descending the great stream or marching along its banks to beyond the junction of the Lipalule, whence he struck across to Lorenzo Marques, in Delagoa Bay. The middle part of the Limpopo, between the Tuli and Lipalule, was found to be encumbered with rapids and waterfalls, some of which, especially the cataracts called Tolo-Azime, were truly magnificent, the river, after a series of rapids five miles in length, here plunging over a ledge into a deep chasm. These falls mark the spot where the Limpopo leaves the great interior plateau of Africa and descends abruptly into the plains which extend henceforth to the sea. The paper described the country traversed as rich and abundant in game of all descriptions.

Mathematical Society, November 9.—Dr. Spottiswoode, president, in the chair. The following gentlemen were elected to form the council for the ensuing session:—President: Dr. Spottiswoode. Vice-Presidents: Profs. Cayley, Henrici, H. J. S. Smith, and Mr. S. Roberts. Treasurer: Dr. Hirst. Honorary Secretaries: Messrs. M. Jenkins and R. Tucker. Other members: Profs. Clifford and Crofton, Dr. Sylvester, Hon. J. W. Strutt, Messrs. T. Cotterill, Merrifield, Stirling, and Walker. Mr. A. Freeman was proposed for election. It being unanimously agreed upon that the number of honorary foreign members should be increased to six, the president read out the names which the council recommended for nomination, viz.: Dr. Clebsch, M. Hermite, Prof. Cremona, Dr. Hesse, and Prof. Betti. The only foreign member at present is M. Chasles. Dr. Sylvester then gave an account of his communication "On the partition of an even number into two primes." In one of his minor papers Euler has enunciated as a theorem, resting entirely on intuition from a comparatively small number of instances, that every even number may be decomposed into a sum of two primes. The object of Dr. Sylvester's communication was to obtain some measure of the probable number of ways in which such decomposition can be effected for any given number; if it can be shown to be probably greater than the square root of the number itself, it will follow from generally admitted principles of the theory of chances, that the probability of the theorem being universally true above any assigned limit, if *proved* to be true up to that limit, may be represented by an infinite product of terms, which will approach as near as we please to unity the higher the limit in question is taken. The mere fact of the theorem, as Euler gave it, being proved up to 100,000,000, or any other number however great, would leave the probability of its being universally true, absolutely zero, just as the fact of the sun having risen 100,000,000 times would not contribute an atom of probability to the supposition that it would continue to rise for all time to come. In the case before us, on the contrary, the probability of the theorem being universally true by a sufficiently copious induction, may be made to approach as near as we please to absolute certitude. The author considers that he has established beyond the reach of reasonable doubt that the magnitude which represents the mean probable value of the number of modes of effecting the resolution of a very large even number into two prime numbers is that of the square of the number of primes inferior to the given number divided by the number itself, or which (thanks to the discoveries of Legendre and Tchebicheff) we know to be the same thing, the number of the decompositions in question bears a finite ratio (assignable within limits) to the number to be decomposed, divided by the square of its Napierian logarithm. If we agree provisionally to call pre-primes in respect to n , those numbers which are prime themselves, and also when subtracted from n leave prime remainders, the author shows that the probable number of such pre-primes (*i.e.*, the most probable value attainable under our present conditions of knowledge) may be found approximately by multiplying the number of ordinary primes inferior to n by the product of a set of fractions, depending in part on the magnitude and in part on the constitution of the number n . If n is the double of a prime, the product in question is got by multiplying together all the quantities $\frac{p-2}{p-1}$ where p is every odd prime between unity and the square root of n ; but if n itself contains any such

primes among its factors, then the corresponding factors are to be omitted out of the product. We thus see that if two even numbers of considerable magnitude lie adjacent or tolerably near to each other, one of which is the double of a prime, but the other six times a prime, the number of preter-primes relative to the latter will be about twice as many as those relative to the former. For the purpose of greater simplicity of explanation, the formula of approximation has been stated above with less accuracy than it admits of being stated with. Instead of the total number of odd primes being multiplied by the product of factors last described, those only should have been taken which are not intermediate between 2 and $\sqrt{n}$, and the result so modified should have been stated to be the probable value not of the total number of preter-primes, but only of such of them (by far the larger number) as are not of the excluded class above described, nor subtracted from n , give rise to remainders belonging to such class. The author has found by actual trial on an extensive scale, that the estimated values of the number of decompositions never differ by more than a moderate, and in some cases exceedingly slight, percentage from their actual values determined by the use of Borchardt's tables. The same methods enable him also to assign a probable value to the number of modes of resolving an odd number into the sum of one prime and the double of another, and in general lead to an approximate representation of the number of solutions in prime numbers of any system of linear equations of which the total number of solutions is limited, and even to resolve approximately such questions as that of determining how many prime numbers there are inferior to a given limit, which are followed by prime numbers differing from them by any assigned interval. Since the communication made to the Mathematical Society, the secretaries have been favoured with a note from which they understand that Dr. Sylvester has verified his results by quite a different method. The exact number of the solutions of the equation $x + y = n$ in prime numbers may be expressed algebraically by means of the method of generating functions in terms of the inferior primes to n . The expression will be found to consist of two parts, one a constant multiple of n , the other, a function of the roots of unity corresponding to the several inferior primes and their combinations. The former non-periodic part may obviously be regarded as the even value of the expression, and Dr. Sylvester has found that it is identical with the value obtained by the method of averages previously employed. In order to prove strictly Euler's theorem, it only remains to show that the entire expression can never become zero. This Dr. Sylvester believes he has the means of doing, and at the same time of assigning exact limits to the number of solutions in question; but in a matter of so much moment, and of such singular interest, does not wish to express himself in a more decided manner, until he has had the opportunity of subjecting his method to a further rigorous examination.

Royal Astronomical Society, November 17.—Mr. W. Lassell, president, in the chair. The Astronomer Royal showed a drawing of Encke's comet made by Mr. Carpenter of Greenwich; it gave the impression of a somewhat shuttlecock-shaped nebulous haze, with two wings of much fainter light, extending on either side, giving a flattened appearance to the head of the comet. Dr. Huggins made a drawing which coincided in all essential particulars with that of Mr. Carpenter. He thought that he had detected a very minute but distinctly-marked nucleus in the paraboloid-shaped head of the shuttlecock. The whole light of the comet was very faint, but he had succeeded in obtaining its spectrum, which, as in the case of that of Comet II, 1868, consisted of three bands, apparently identical with the bands in the spectrum of the vapour of carbon. The middle band situated near "little b" was much brighter than than the other two, and he was quite satisfied of its identity with the middle bands of carbon vapour; the two outlying bands were much too faint for him to speak with confidence of their identity, but they appeared to correspond. The Astronomer Royal showed a celestial globe, on which he had fixed a small white wafer in the place occupied by the sun, and a piece of white paper cut out to represent the comet. He pointed out that its longer axis was directed almost exactly to the sun, and that its head and nucleus were turned away from the sun. This appears to be the almost universal rule with the smaller class of comets. Unlike the sheep of little Bo Peep they carry their tails before them, and not until their smaller fan-shaped appendages have been well warmed by the sun's rays, do they begin to shoot out large tails in the other direction.—A paper was read by Prof. Grant, in which he

pointed out that as early as the year 1852 he had recognised the continuity of a red envelope enclosing the sun, of which the prominences were merely the more elevated portions; he had come to this conclusion from a comparison of the observations made during the total eclipses of 1842 and 1851.—A discussion then followed as to whether there were any permanent markings upon Venus. Dr. W. De la Rue and Mr. Browning affirmed that they often saw spots and other irregularities of surface. The authority of Mr. Dawes, and many other observers of note, was cited to the contrary.—Some careful drawings of the Zodiacal light as seen by Captain Tupman while cruising in the Mediterranean were handed round. It was pointed out by Mr. Ranyard that the axis of symmetry of the light was in many instances greatly inclined to the ecliptic, and that the distance of the node of the axis from the sun was in some instances more than 40°.

ARCTIC EXPLORATION

IN 1865 Captain Sherard Osborn proposed an exploration of "the blank space around our Northern Pole," by a route which he and his brother Arctic explorers, from considerations based on the history of the subject during three centuries, and on their own experience in the ice, were convinced was the best, and the most sure to lead to useful scientific results.

Their reasons for adopting the views then set forth, the correctness of which has since been confirmed by Swedish and German explorers, were as follows:—

The immense tract of hitherto unvisited land or sea which surrounds the northern end of the axis of our earth, is the largest, as it is the most important field of discovery that remains for this or a future generation to work out. The undiscovered region is bounded on the European side by about the 80th parallel of latitude, except where Parry, Scoresby, and a few others have slightly broken through its circumference; but on the Asiatic side it extends south to 75° and 74°, and westward of Behring's Strait our knowledge is bounded by the 72nd parallel. Thus in some directions it is more than 1,500 miles across, and it covers an area of upwards of 2,000,000 square miles, with the North Pole towards its centre. Unlike the ocean-girt region of the Southern Pole, the northern Polar region is surrounded, at a distance of about 1,000 miles from its centre, by three great continents, while the glacier-bearing mass of Greenland stretches away towards the Pole for an unknown distance. There are three approaches by sea to this land-girt end of the earth, namely, through the wide ocean between Norway and Greenland, through Davis Strait, and through Behring's Strait. One wide portal and two narrow gates.

It was through the wide portal that men naturally sought, in the first instance, to reach the mysterious region of the Pole; and they continued to persevere in that direction until experience had taught those who were capable of learning from it that, as in other cases, the longest way round was the shortest way home. The first true Arctic voyager was William Barents, who sailed from the Texel in 1594. He discovered all we now know respecting the Spitzbergen seas; first, the open lane of water which almost always enables vessels to sail up the western side of that land; second, the impenetrable Polar pack to the north, and between Spitzbergen and Novaya Zemlia; third, that the young ice formed in the early autumn and rendered the sea unnavigable; and, fourth, that winds and currents caused open water even in the winter and early spring, but again drove the ice upon the coast at every change of wind. Hudson, in two voyages, explored the whole of the pack-edge from Greenland to Novaya Zemlia, and found it to be impenetrable; and many others followed him with the same result. In later years four expeditions sailed up the west coast of Spitzbergen beyond the 80th parallel, and Dutch and English whalers collected a vast mass of information, which has been ably brought together by Scoresby and Jansen, and which pretty well exhausts the subject.

During the winter and early spring the ice extends in a

line from the east coast of Greenland to the northward of Jan Mayen Island, crossing the meridian of Greenwich between the 71st and 72nd parallel, then passing up north for several degrees, and leaving a deep bay, and finally stretching away to Novaya Zemlia. The deep bay in the ice, left to the eastward of the Greenwich meridian in the winter, is probably caused by the so-called Gulf Stream. It forms the route by which the whalers proceed to their fishing-ground, and is known as "the whale-fisher's bight." In the spring the Polar pack begins to drift to the southward and westward, so that the western or lee sides of large masses of land, such as Spitzbergen, are usually left with open navigable lanes of water; while the eastern or weather sides are generally close packed with ice. The pack, consisting of vast fields of thick ribbed ice, has never been penetrated, though whalers annually sail through streams of lighter floes until they reach its edge. The Polar pack is met with in different parallels according to the season and the meridian. Between Spitzbergen and Novaya Zemlia it is usually in 75° or 76°; but occasionally vessels have reached as far as 81° without encountering it, and in the very exceptional year when Parry attempted to reach the Pole, he was only coming in sight of it at his extreme point in 82° 43', although he had been travelling for 92 miles over closely-packed floes of ice through which no steamer could have forced her way. In another exceptional year, that of 1806, Scoresby sailed along the edge of the pack for 300 miles, between the parallels of 81° and 82°; and at his extreme point in 81° 30', on the meridian of 19° E., the margin of the ice trended to E.N.E., while to the eastward there was an open sea to the horizon, with no ice blink. Farther east a latitude of 82° or even 83° might possibly have been attained in that year, before arriving at the edge of the Polar ice. Analogous conditions of the ice were found by James Ross in the Antarctic sea. He sailed through pack ice met with in the 62nd parallel, which was drifting north, and then reached the edge of the impenetrable Polar pack which he found extending for 400 miles in a wall 150ft to 180ft. high in the parallel of 78° 30' S. In the northern sea the Gulf Stream flows up until it meets the ice-laden Polar current between Spitzbergen and Novaya Zemlia. It keeps the ice off the shores of Norway and Lapland, but the parallel on which the warm current meets the ice-bearing stream, and is cooled down to 27°, varies in different seasons. Even if it were possible, by extraordinary luck, to force a steamer through the pack to the open water supposed to be left by its southerly drift, the autumn would be so far advanced by the time she reached it that young ice would be forming on the surface, and all navigation would be at an end. In 78° N. ice forms on the sea during eight months in the year, and Scoresby often saw it grow to a consistency capable of stopping the progress of a ship, even with a brisk wind blowing.

These facts, the results of thousands of observations extending over many years, proved that an attempt to force a vessel through any part of the Polar pack between Greenland and Novaya Zemlia was not the best way to explore the unknown region of the north.

Sir Edward Parry was the discoverer of the true method of Polar exploration, by sledge travelling. He proposed to attempt to reach the North Pole, in 1827, by travelling

with sledge boats over the ice to the north of Spitzbergen; and he actually reached the farthest northern point that has yet been attained by civilised man. But the rainfall was exceptional that year; and the ice was in a very unfavourable condition. It was not until he reached $82^{\circ} 43' N.$ that he described the strong yellow ice blink overspreading the northern horizon, and denoting the vast ice fields over which he hoped to travel. His provisions then only sufficed to take him back to his ship, and he was obliged to return. He made a mistake in the route and in the time of year; but he has the credit of having been the pioneer of Arctic travelling, and of having pointed out the true way of exploring the unknown Polar region.

In deciding upon the best route, Sherard Osborn had his own great experience in the ice, and the recorded observations of Parry and Ross, and of generations of previous explorers to guide him. The first Arctic canon is, "Never take the pack if you can possibly avoid it, but stick to the land floe." The second is, "Reach the highest possible parallel in your ship, and then complete the exploration by sledge travelling." A glance at a Polar chart will show that the first canon can only be followed by passing up the west coast of Spitzbergen, or the west coast of Greenland. But the Greenland coast reaches a higher parallel than that of Spitzbergen. Therefore the Greenland coast is the route to follow,—up Smith Sound and Kennedy Channel to the farthest point attainable. A vessel can almost always reach Smith Sound in one season, for the same reason that a vessel seldom finds it difficult to sail up the west coast of Spitzbergen, namely that she is to windward of the ice. She sticks to the land floe and lets the pack drift past her. Out of thirty-eight exploring vessels that have gone up Baffin's Bay from 1818 to 1860, only two have failed to reach the open water at its head which leads to Smith Sound, before the navigable season was over. From the position that may thus always be reached by an exploring ship, sledge parties could be despatched to the North Pole and back—a distance of 968 miles—a distance often exceeded by the Arctic sledge travellers in search of Franklin; as well as to complete the exploration of the northern coast of Greenland, and of the land to the westward. Such was the plan proposed by Osborn in 1865. It was feasible; it promised useful scientific results; it ensured a vast accession of new geographical knowledge; and the Government could scarcely have refused to adopt it if there had been unanimity in the counsels of geographers and explorers.

But a fatal apple of discord was thrown into their midst by the eminent geographer of Gotha; and the Admiralty seized on this want of unanimity as an excuse for postponing indefinitely the consideration of the subject. Dr. Petermann has done serious injury to the cause of Arctic exploration by thus forcing his theories into notice at a time so extremely inopportune. It was in 1852 that he first brought forward the theory that there is an open navigable sea between Spitzbergen and Novaya Zemlia leading straight to the Pole especially late in the autumn. He assured the Admiralty that the *Erebus* and *Terror* were somewhere near the Siberian coast, and that they could be reached without serious difficulty by this wonderful route. Had

he been listened to, and had our gallant countrymen been then alive, it makes one shudder to think of the consequences if the searchers had thus been led off the true scent. That time no harm was done. But in 1865 Dr. Petermann found more willing listeners. He again declared that the sea between Spitzbergen and Novaya Zemlia was the easiest and most navigable entrance to the unknown region; and he added two new discoveries; first, that Parry, at his farthest point, found a perfectly navigable sea extending far away to the north; and second, that Smith Sound is a *cul de sac* (of which he published a map), and unconnected with the Polar Ocean. The first discovery is surely a dream, for Parry himself saw a strong ice blink overspreading the northern horizon at his farthest point. The second exists only in Dr. Petermann's imagination, and, before he announced it, he should have called to mind the fate of a certain range of mountains named after the late Mr. Wilson Croker. The only tangible grounds for believing in an open Arctic ocean navigable to the Pole, are that the Russian explorers Hedenstrom, Anjou, and Wrangell, saw patches of open water and rotten ice off the northern coast of Siberia in March and April, and that Dr. Kane's ship's steward reported having seen a wide extent of open water in June to the north of Smith Sound. The Russian *polyntias* or water holes are in all probability caused by winds and currents acting on a shallow sea, and, so far as we yet know, they are merely local. The same thing was observed by Barents off Novaya Zemlia in November, and an off-shore wind will carry the ice from the head of Baffin's Bay at all seasons. But this does not make the sea navigable. The open water of Dr. Kane's steward in June was only what might be expected at that season, though Dr. Hayes found the same spot covered with ice within a few days of the same time of year, in 1861. Dr. Petermann's arguments unfortunately had the effect of destroying that unanimity, without which it was hopeless to attempt a successful representation of the importance of Arctic exploration at the Admiralty.

The ostensible reason given by the Duke of Somerset for postponing the question, was in order that the results might be learnt of a Swedish expedition then engaged in exploring Spitzbergen, under the direction of Professor Nordenskiöld. Those results fully confirmed the correctness of Sherard Osborn's views. Nordenskiöld reported that no vessel could force its way through the closely-packed ice north of Spitzbergen; but that the ice moves, after long southerly winds, considerably to the north. "All experience seems to prove," adds Nordenskiöld, "that the polar basin, when not covered with compact, unbroken ice, is filled with closely-packed, unnavigable drift-ice, in which some large apertures may be found; though in favourable years it may be possible to sail a couple of degrees north of the 80th parallel in September or October."

Dr. Petermann has since promoted the equipment of Arctic expeditions, which were expected to prove his theory, and to disprove the opinions of Captain Osborn. But he has sent prophets to curse his opponent, and behold, they have blessed him altogether! In 1868 the first German Arctic Expedition sailed under the command of Captain Koldevey, with instructions to penetrate as far north as possible along the east coast of Greenland, or to try to reach Gillis Land, east of

Spitzbergen. They made four attempts to press through the ice, and failed, as all their predecessors had failed. But it is stated by German writers that this expedition attained the highest point ever reached by a sailing vessel, namely, $81^{\circ} 5' N$. This is a mistake. Parry reached $81^{\circ} 5' N$. in the *Hecla*, and $81^{\circ} 13'$ in his boats, and Scoresby reached $81^{\circ} 30' N$. in 1806, on board the *Resolution* of Whitby. In 1869 the second German expedition sailed, also under command of Captain Koldewey, with instructions from Dr. Petermann to penetrate through the belt or girdle of ice which encircles the open polar basin of his imagination, to winter at the pole, and then to sail across it and explore the Siberian islands. All very easy to write at Gotha! But, as usual, Captain Koldewey was stopped, as all his predecessors had been, by the closely-packed ice, and wintered on the east coast of Greenland, at a part which was visited by Sabine and Clavering in 1823. The German explorers made careful scientific observations, and partly examined a very interesting navigable fiord running into the heart of Greenland. The expedition returned to Bremen in September 1870, and the experience acquired by two seasons in the ice has enabled its talented and energetic commander to form an authoritative opinion on the best route for north polar exploration. Captain Koldewey, the first German authority on Arctic navigation, fully concurs with Captain Osborn that the way to explore the unknown region is by sending an expedition up Smith Sound.

The other Arctic voyages that have been made since 1865 are of minor importance. In 1869 Dr. Bessels crossed the sea between Spitzbergen and Novaya Zemlia, and met with field ice between 76° and $77^{\circ} N$. in August. Norwegian fishermen named Ulve, Carlsen, and Johannesen, found the Sea of Kara comparatively free of ice in 1869—70, and the latter is said to have sailed round Novaya Zemlia. In 1870 Count Zeil and von Henglin made some useful observations on the east side of Spitzbergen during a yacht voyage, and obtained a sight of the still more eastern Gillis Land. In the present year Lieut. Payer, who served under Captain Koldewey, made a voyage towards the Polar pack, between Spitzbergen and Novaya Zemlia, and he reports having nearly reached the 79th parallel, between the 40th and 42nd meridians east from Greenwich, and again in $60^{\circ} E$., finding open water. But Mr. Smith, an English yachtsman, in the same season, was more lucky or more adventurous. He reached the latitude of $81^{\circ} 13' N$., the highest that has ever been ever observed on board a ship. Scoresby, indeed, reached an *estimated* latitude of $81^{\circ} 30'$ on May 24, 1806, but his highest *observed* latitude was $81^{\circ} 12' 42''$ on the 23rd. These voyages merely confirm the observations of Nordenskiöld and earlier explorers, that, though the pack is usually met with, east of Spitzbergen, between 75° and $77^{\circ} N$., it may not be reached in exceptional years until the 81st, or even the 82nd parallel is attained.

Such have been the results of Arctic exploration since Sherard Osborn submitted his proposal in 1865. They fully confirm the correctness of his views; and the best English and German Arctic authorities are now in complete accord. There is, therefore, no longer any reason for postponing the consideration of this question. Six years have been wasted, and the men who were available to lead an expedition in 1865, may be unable to do so

now. But the navy of England still abounds in the same stuff that made a Parry, a James Ross, a McClintock, and an Osborn in former years: and it must always be remembered that it is out of young Arctic explorers that Nelsons are formed. The arguments for Osborn's scheme of exploration by Smith Sound are now strengthened by the experience of Nordenskiöld and Koldewey. The same evidence of the important scientific results to be obtained by an Arctic expedition that was produced by the highest authorities in 1865, is forthcoming now. The argument that such enterprises in the pursuit of Science have an excellent effect upon the naval service is as strong now as it was then. We may, therefore, reasonably hope that (the Duke of Somerset's reason for postponing the question having been entirely removed) the Admiralty would take the subject of Polar exploration into favourable consideration, if the scientific societies once more submitted it, with the same arguments as were used six years ago.

C. R. MARKHAM

ORD'S NOTES ON COMPARATIVE ANATOMY

Notes on Comparative Anatomy: a Syllabus of a Course of Lectures delivered at St. Thomas's Hospital. By W. M. Ord, M.B. (Churchill, 1871.)

DR. ORD may be congratulated on having put together this compact, lucid, and well-arranged Syllabus. It is well adapted to serve as a framework, for lecturers on Comparative Anatomy to fill up, and students may also use it to refresh the memory when once stored with more slowly acquired information. The abuse of it will be for men to bolt this condensed extract of scientific food in order to produce it again under examination. The author seems to have foreseen this danger, and not only warns against it, but has been careful to preserve the bald and dry style which ought to repel those who do not know how to use the book as he intends. Still, experience of the way in which Prof. Huxley's "Introduction to Classification" is misused by being literally learned by rote, shows to what ill uses such compendia may be put.

The Syllabus begins with a short summary of the distinctive characters of the organic and of the animal kingdoms, followed by a scheme of classification which follows that of the introduction just referred to. The several animal classes from Protozoa to Mammalia are then treated, so that the arrangement is a zoological one. It would perhaps have been better if the author had devoted less space to the enumeration of the characters of orders and classes, since these are found in other manuals, and if anatomical points of difficulty had been more fully explained. For example, more detailed exposition of subjects like the morphology of the compound Hydrozoa, the development of Echinoderms, and the formation of the placenta, would have been exceedingly valuable. For such an object, however, diagrams are almost essential, and, accepting Dr. Ord's plan, it must be admitted that he has carried it out with a due regard to symmetry. The only subject which the Syllabus appears comparatively to neglect is the difficult but important one of Embryology. The account given of the Annulata and Entozoa is particularly clear and excellent. The following extract is a fair specimen of the author's style and method:—

"CL. BRACHIOPODA.—Solitary bivalves, in which the

valves are dorsal and ventral, like the two parts of a cabriolet in relation to the animal within, instead of lateral (wing-like) as in Lamellibranchs. Valves joined by hinge or not; never with elastic spring. When not hinged, the valves imperforate; when hinged, one, the larger, is perforate for the transmission of an anchoring ligament, in the non-hinged the ligament passes out between the valves. The class is divided into two orders or subclasses, — the Articulate and the Inarticulate. The Articulate, of which Terebratula is type, have usually curious shelly processes developed from the inner surface of the imperforate valve for the support of the arms, and have in the adult condition no anus; the Inarticulate, of which Lingula is type, have no arm-supporting processes and have no anus.

The account given of the vertebrate skeleton, and especially of some disputed questions of homology, is not so satisfactory as most other parts of the Syllabus. It may be doubtful whether it is desirable to introduce into elementary lectures the difficult subject of the representatives of the tympanic bones in the lower vertebrata; but if so, it is quite useless for men to learn to repeat the "views" of Owen, Huxley, Peters, Parker, and Humphry, and to assign the right view to the right man, unless they are familiar with the facts of embryology, on which alone a judgment can be formed. Now, whether the incus belongs to the first visceral arch, as here stated (p. 113), or to the second, as is believed by some original observers, makes all the difference as to the correctness or incorrectness of the statements which follow. Again, whatever doubt still remains as to the homologies of the pelvis and shoulder girdle, surely no one who has read Prof. Flower's paper on the subject and his subsequent remarks in the "Osteology of the Mammalia," can accept the correspondence of the pubes with the clavicle. The former may very probably answer to a procoracoid, as Gegenbaur and other anatomists suppose, but its mode of development its position in reptiles, and its relation to the great nerves and vessels of the hind limb, are all conclusive against the homology given in p. 116, and more fully in p. 146. No reason is assigned for the query affixed to the statement (p. 171) that the elephant's placenta is deciduous and zonary, which zoologists have hitherto accepted on the testimony of more than one careful and independent observer. The statement as to the number of the cervical vertebrae in mammalia (p. 172) is not exact. No Cetacean has yet been found in which the full number cannot be distinguished, however much fused together the vertebrae may become. On the other hand, the manati has never more than six, and the same appears to be true of one species of *Choloepus* (not *Choleopus*).

No mention is made of the order Dipnoi in the classification of fishes taken from Müller (p. 117), or again in the characters of the orders (pp. 133-135). So remarkable a form as *Lepidosiren* should not have been omitted, even if Dr. Ord accepts the conclusion which Dr. Günther has very lately stated in these columns (vol. iv. Nos. 99 and 100). The new genus *Ceratodus*, now that its anatomy has been so fully investigated, forms no doubt a very complete link between the Ganoids and the Dipnoi, and many zoologists will agree with the classification proposed in the admirable paper just referred to; but books intended for students should scarcely pursue the "latest views" so closely.

In conclusion it is only fair to repeat that these Notes

deserve commendation for their general accuracy, and contrast very favourably with some other manuals for students on the same subject. They will, if well used, be valuable to learners, and perhaps still more so to teachers.

P. H. PYE-SMITH

OUR BOOK SHELF

Note-book on Practical Solid or Descriptive Geometry, containing Problems with help for Solutions. By J. H. Edgar, M.A., Lecturer on Mechanical Drawing at the Royal School of Mines, &c., &c., and G. S. Pritchard, late Master for Descriptive Geometry, Royal Military Academy, Woolwich. (London and New York: Macmillan and Co., 1871.)

WHEN our Civil and Military Engineering Examinations are daily making larger demands for geometrical proficiency a new and exceedingly lucid *Note-book on Descriptive Geometry* comes well-timed. Though much has been done to expand this collateral offshoot of geometrical science since M. Monge, of the Ecole Polytechnique, first started it, the co-ordinative characteristic of a science has hitherto been wanting; it has contained, doubtlessly, all the abstract principles of orthographic projection, but principles, to be available, must be interdependent and derivative. Messrs. Edgar and Pritchard have felt this deficiency, and have done much to remove it. Their book, unlike the majority of cheap hand-books, is neither "patchy nor scrappy," but a continuous and coherent whole. "Elementary Explanations, Definitions, and Theorems" come first, followed by twenty-eight problems on "The Straight Line and Plane;" to these succeed Solids, first singly, and then in "Groups and Combinations." In like logical order we next have "Solids with the inclinations of the plane of one face, and of one edge or line in that face given," and then "Solids with the inclinations of two adjacent edges given," and, lastly, in this category, "Solids with the inclinations of two adjacent faces given." So far we have the principles of projection in a much more perfectly co-ordinated arrangement than we have hitherto found them in, and we must say that the mere act of mentally assimilating this interdependence of principles would be wholesome discipline, even if it did not, as it unquestionably does, facilitate each successive step in progress, and, most of all, conduce to an integral entertainment of the subject. Again, as naturally derivable from the consideration of the inclined faces of solids, we arrive at "Sections by oblique planes," and "Developments," or the spreading out in one plane of the adjacent faces of such solids; and, finally, the development of curved surfaces. "Miscellaneous Problems" now have place, and amongst them we notice one from the "Science Examinations" of last year. The sequence of the four next chapters is judicious. "Tangent Planes," "Intersections of solids with plane surfaces," "Intersections of solids with curved surfaces," "Spherical Triangles." A short chapter on Isometric Projection (quite as long as it deserves) ends the work, the authors of which we rejoice to find (in these days of "result-seeking") much more desirous of results actual than results visible, and accordingly, foregoing a somewhat too popular profusion of diagrams, which, while it undoubtedly facilitates the bare apprehension of subject-matter, by no means enforces that comprehension of the subject which attends upon the act of accomplishing a mental diagram for ourselves. In this expression of their conviction the authors, we observe, are at one with Mr. Binns, who, with the same sincerity, and for like reason, resisted the systematic use of models in the teaching of "mechanical drawing."

Messrs. Edgar and Pritchard have produced an inexpensive, but a well-digested, comprehensive, lucid, and typographically attractive *vade mecum*.

On the Constitution of the Solid Crust of the Earth. By Archdeacon Pratt, F.R.S. (Phil. Trans., 1871.)

ANOTHER contribution to a subject on which the author has laboured for many years—never perhaps very brilliantly, but always in the main soundly. Such unmitigated nonsense has been talked on the subject of the thickness of the solid crust of the earth, even by scientific men of real power—generally mere mathematicians, sometimes geologists, rarely indeed physicists—and such extravagant views on the subject are still propounded and defended by men like Delaunay, who have done good work in closely allied questions, that it is really refreshing to read Archdeacon Pratt's paper. Yet its tone is somewhat hesitating, almost apologetic, and he finally arrives at the conclusion that what seems to us to be at least a natural assumption to make at starting (*viz.*, that a level surface may be drawn, not very many miles under the surface of the earth, such that in spite of hills and ocean beds the amount of matter shall be the same in every vertical line between these two surfaces) leads to results not after all very inconsistent with those derived from actual pendulum observations made over the Indian Continent. Sir W. Thomson's bold investigation of the tides in the solid earth, due to elastic yielding, furnishes us with by far the most powerful mode of attacking the general question which has been devised since Hopkins's celebrated suggestion of the information to be derived from precession and nutation; and it is to be hoped that the labours of the Tidal Committee of the British Association will soon furnish, from observation, the data required for its numerical application.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Instruction in Science for Women

IN thanking you for the useful account given in your last number of the various attempts being made in different parts of England to improve the scientific education of women, may I give you a few more details of the effort now being made at Cambridge to assist the training of those ladies who live too far from any educational centre to be able to get oral instruction?

Correspondence classes have been formed in some of the subjects selected for the University Examination of Women, and the teachers (chiefly resident fellows of colleges) are attempting to assist the reading of their correspondents by means of advice, examination papers at fixed intervals, and free criticism.

Of course this scheme cannot offer the advantages which the lecture systems of London, Edinburgh, and Cambridge itself afford; but that it does meet a real want in what I may venture to call the "rural districts" is shown by the fact that more than seventy women have joined the scheme within a month. Among the subjects of which you take notice in your article, Mr. Stuart of Trinity has undertaken the higher mathematics, Mr. Hudson of St. John's the arithmetic (how wofefully ill-taught in the average girls' school no one but the examiner can appreciate), Mr. Bonney of St. John's the geology, and myself the botany. I should add that it is not at all the wish of the promoters to limit the scheme to possible candidates for the Cambridge examinations, but as far as possible to assist any woman who may be struggling with the difficulty of reading a new subject by herself.

All women who wish to avail themselves of this scheme are requested to communicate with the Hon. Sec., Mrs. Peile, of Trumpington, near Cambridge. F. E. KITCHENER

Rugby, Nov. 25

True and Spurious Metaphysics

DR. INGLEBY is evidently a strategist of no mean order. The appalling suddenness of his totally unexpected personal attack, and the skill with which he has almost made it impossible for me to reply without laying myself open to the charge of Egotism (second only in gravity to a charge of Immorality), shows that he is a good deal more than a mere metaphysician. Of metaphysics anon—meanwhile about mathematicians.

I altogether repudiate the Trichotomy, as Dr. Ingleby gives

it. The man is either a Mathematician or a Non-Mathematician. There is no intermediate class. Merely to be able to integrate, to solve differential equations, to work the hardest of Senale-Houes Problems, &c., &c., is not to be a Mathematician. To deserve the name a man *must* have some of the creative faculty; must be the *Ποιητής*, if ever so little. And to be a Creator in this sense it is not necessary that one should have devised a new Calculus. Are Stokes, Thomson, Clerk-Maxwell on the one hand, or Cayley, Sylvester, Clifford on the other mere Experts? Yet there can be no doubt that, in Dr. Ingleby's classification, this is their rank.

As regards Hamilton's having placed Metaphysics higher than Mathematics, I may avail myself of the remark, which I heard not long ago in conversation, that "what Hamilton thus exalted was the Metaphysics of the great thinker (and Mathematician) Kant, not the common Cant of Metaphysicians." The distinction implied in this poor pun is one of enormous importance. For there are Metaphysicians and Mathematicians. Here I am happy so far to agree with Dr. Ingleby, and I shall dichotomise, but not quite as he proposes.

Metaphysicians A. The genuine article. To this class all men worthy of the name of Mathematicians necessarily belong, as do the higher Physicists, &c., &c., such as Faraday. Hence, of course, Archimedes, Descartes (Cartesius, not *Cartes*!), D'Alembert, Hamilton, &c., &c., appear in the list. Leibnitz was, I fear, simply a thief as regards Mathematics, and in Physics he did not allow the truth of Newton's discoveries; so he does not belong to this class.

Metaphysicians B. The spurious article, which has somehow managed to arrogate to itself the title belonging of right to the genuine one. Test this class by what it has to show "even in the present advanced state of metaphysics" (as Dr. Ingleby has it): what have we but stagnation, ropes of sand, bitter quarrels as to the meaning of unintelligible words, and, above all, complacent pride in being "not as other men" but dwellers in a sublimer sphere? Even Longfellow's idiotic "Youth," who ascends the Matterhorn when "the shades of night are falling fast," carrying a pompous "banner with a strange device," does not so ridiculously contrast with the practical Wympyer and Tyndall carrying their ropes and ice-axes, as do the Metaphysicians B with the Metaphysicians A—the Drones with the Working-Bees.

When I asked for the name of a Metaphysician who was also a Mathematician, it was of course of Class B that I spoke, the class containing Hegel and Sir William Hamilton, Bart, (the former of whom proved that Newton did not understand Fluxions nor even the Law of Gravitation, while the latter asserted that the pursuits of the Mathematician reduce him either to passive Credulity or to absolute Unbelief!), the class which is popularly, and (almost *therefore*) erroneously, known by the name.

P. G. TAIT

"Wormell's Mechanics"

I REQUEST to make a few observations upon Mr. Wormell's letter in your last number. I shall refer to the paragraphs he has numbered.

1. It is true that, by a collation of two passages, a really intelligent student might be able to eliminate the error from the first statement in Mr. Wormell's book to which we have taken exception. I consider that such collation should be unnecessary in a text-book.

2. A mathematician would, of course, understand what Mr. Wormell means, however he might disapprove of its logic; but Mr. Wormell writes for beginners, and should state his demonstrations without ambiguity.

4. "Curious" is not the adjective we are tempted to apply to such a blunder as that on p. 112. This has not been corrected in even the second edition of the book, notwithstanding the "schoolboy's" aid.

5. We had read Sec. 71, and consequently made the remark about the block and tackle to which Mr. Wormell objects. We now re-assert that the effect of friction upon the mechanical powers is too important to have been omitted in a book professing to treat of Theoretical and Applied Mechanics.

Nov. 25

THE REVIEWER

Solar Halo

THE following description and drawing of a solar halo and mock suns seen on the morning of the 13th inst., by the Rev. J.

A. Lawson, at Brancepeth, near Durham, is so perfectly similar to its appearance as drawn and described to me by another observer at Woodburn, at the same hour on the same morning, about twenty miles north-west from Newcastle, and about thirty miles from Durham, that its unusually bright appearance near Durham may not improbably correspond with equally favourable views of it obtained by observers at more distant places. The sky, which remained clear during the day, clouded over towards midnight on the 13th, and the stars were completely hidden during the remainder of the night. A slight rain, which began in the morning, also continued to fall during the day of the 14th, and the sky here remained entirely overcast on that evening until after midnight. Shortly before four o'clock on the morning of the 15th the clouds cleared off, and the appearance of several meteors, one of which was as bright as Jupiter, gave evident signs of the progress of the November star-shower. The perfect clearness and darkness of the sky, in the absence of the moon, at the same time gave especial brightness to the meteors and to their phosphorescent streaks. Between four o'clock and the first approach of daylight, at six o'clock, thirty-two meteors were counted, or at the rate of sixteen per hour, of which three were as bright, or brighter, than first magnitude stars, nine as bright as second, six as bright as third, and eight no brighter than stars of the fourth or lesser magnitudes. Twenty-six of these meteors were directed from the usual radiant point in Leo, which on this occasion, although not very well defined, appeared to be approximately close to the star Zeta, in Leo's sickle. About one-half of their number left persistent streaks, which sometimes appeared to grow brighter after the meteors had disappeared, and I vainly endeavoured to bring them into the field of view of the direct-vision prisms of a small spectroscope, the duration of the brightest streaks noted scarcely ever exceeding one or two seconds. A very brilliant meteor, casting around a flash like that of lightning, was seen here shortly after nine o'clock on the evening of the 13th (and its appearance was also noted at Woodburn), traversing the north-west sky. The particulars, imperfect as they were, unfortunately, rendered by the cloudy weather, are the only descriptions of the November star-shower which its appearance here has hitherto enabled me to supply.

Newcastle-on-Tyne, Nov. 17

A. S. HERSCHEL.

"I had occasion to be at the station at 8.30 A.M. I then first saw them. The night had been hard frosted with a clear sky. The ground was covered with hoar. There was no mist. The sun was intensely bright, but the air was very chilly. I went home and looked at my thermometer in the porch at the north side of my house; it stood at 29° F. I then went to the top of a hill to have a better view. I instantly made a sketch of the phenomenon,

a copy of which I enclose. The lower part of the circle was hidden by a bank of dark clouds. The upper part presented the most marked appearance, and was intensely white. The lump to the north side was more intense in colours than the southern, but both were distinct as to quantity of reflected light. The colours were prismatic, but a bright amber prevailed. The disappearance began at a few minutes before ten, and by five minutes past ten all had cleared away. With the exception of the bank of clouds beneath, there were only a few pencils of cirrus cloud in the sky.

"Brancepeth, Durham, Nov. 13"

Paraselenae

IN NATURE, Nov. 9, there appeared the description of a remarkable paraselenae observed at Highfield House on the 25th of Oct. A similar phenomenon was seen at Penrith the same night from about 10.30 to 11. As this, however, differed altogether in detail from that observed by Mr. Lowe, I now offer a sketch of what we saw.

Thin mists and white flying seeds travelled across the sky. A luminous ring of perhaps at a guess 150° radius encircled the moon. Within this was a cross of the same brightness as the encircling ring. The bars of the cross were to the eye horizontal

and vertical, intersecting in the moon. Where the horizontal bar cut the luminous ring there were bright patches of light (mock moons), rivaling the moon, as seen through the mist, in brilliancy, but without its defined outline. Where the vertical bar cut the ring there was no increase of brightness. Such a portent in ages gone by might well have filled crusaders with hope, and perhaps thus turned the tide of battle on the morrow. We may make a useful note for future guidance by remarking what followed its appearance in this district. Up to the 25th we had for some time had very fine weather. After the 25th we had five stormy days of wind and rain.

T. MCK. HUGHES

The Solar Parallax

PROF. NEWCOMB wishes apparently to make this discussion as personal as possible. Though I do not intend to follow him in this respect, I must answer him.

He asserts that my abstract of his notes was inadequate; that I "hid the point of the most remarkable of" my "inaccuracies, and ignored the imperfections entirely." This is not so. My abstract was strictly accurate and very much fuller than the utter triviality of his objections warranted. I distinctly stated why I did not discuss the matters which he is pleased to regard as imperfect—his comments being too vague. But this was not ignoring them. His memoranda were not in a state to be printed in full, nor did he even hint that he wished them to be.

As he himself characterises my mistake about his own researches as "the most remarkable of my inaccuracies," it is fortunate that this mistake is also one I am forced to explain at length, owing to the tone Prof. Newcomb has taken respecting it. I certainly did omit a part of Prof. Newcomb's charge; but in his own interest, for it was worded in the very tone to which I now take exception.

In the first place, it is not to be inferred that, because an author comments on such and such a work, he thereby wishes it to be understood that he has himself studied the original memoir in which the work was presented to the world. For instance: many very eminent men have commented on the work of Adams and Leverrier in the matter of Neptune who have not read a line of the original reasoning of these astronomers. That I, of all men (who have expressed something like contempt for memoir-hunting, and have always cared rather to explain methods and describe facts than to write the history of astronomy), should be expected to read every memoir to which I refer, is preposterous in the extreme. It may seem only natural to Prof. Newcomb that when I heard of his having discussed the transit of Venus, I should hurry to obtain his memoir that I might study it *ab initio usque ad finem*; but, as a matter of fact, a paper of the sort, even if placed in my hands, would scarcely tempt me to take up my paper-knife.

Here are the facts of the case.

I read in the *Astronomical Register* a letter which may be called

anonymous, if we please, but which was referred by every one who read it to the Astronomer-Royal for Scotland, who showed not the slightest wish to conceal his identity. Doubtless on hearsay evidence (in which, however, he placed, I am sure, as much reliance as I placed in his own statement), Prof. Smyth asserted that Newcomb had anticipated Stone's labours. I took it for granted that it was so, since I saw no room or reason for doubt. There was my error. But, says Prof. Newcomb, whence comes the value $8^{\circ}87$ "which it will be noted is Mr. Petrie's pyramid value?" and on what does Mr. Proctor found his comments "about my treatment of contacts? I am as much in the dark as ever." I will tell him. The value $8^{\circ}87$ has nothing on earth to do (so far as I am concerned) with Mr. Petrie's pyramid value. It is simply the value insisted upon by Prof. Newcomb in a paper which appeared in the *Monthly Notices* of the Royal Astronomical Society for November 1868; respecting which Mr. Stone remarked (see the same number of the *Notices*) that "the point Mr. Newcomb has raised is a question of only $0^{\circ}04$, viz. between my value and $8^{\circ}87$ —a question, therefore, of comparative insignificance." Most just remark! With my belief as to Prof. Newcomb's prior work, was it wonderful that I concluded that $8^{\circ}87$ was his own pet figure for the parallax? Then it chanced that the Royal Astronomical Society, venturing to ignore Prof. Newcomb's objections, bestowed on Mr. Stone, in 1869, the Gold Medal of the Society for his researches into the Venus transit; and in the remarks which accompanied the presentation, it was stated that all preceding researches were imperfect in this respect, that (to use my own words) "no fixed rule had been adopted for interpreting the observations of internal contact." Prof. Newcomb cannot fail to see how this statement accounts for the estimate (not *my* estimate) of his supposed researches.

As a matter of fact, however—apart from the inference to which Prof. Newcomb is so anxious to give point—I am somewhat hardly treated in this matter. When I came to the part of my book where Prof. Newcomb's supposed researches should be dealt with, I thought thus in my mind: "Assuredly Newcomb has done this thing, for Prof. Smyth says so. Shall I leave his researches unnoticed because I can find no trace of them? That would be scarcely fair. Moreover, he is an American, and to omit all notice of his work will be so much the more objectionable. Verily I will repeat the statement of my esteemed friend at Edinburgh, and I will combine with it the weighty judgment of my friends at the council-board of the Astronomical Society. Thus will the researches of Newcomb be recorded, and due credit be assigned to him for his industry and skill, while yet no undue weight will be given to the numerical result of his labours."

That I thus fell into error I have already admitted. But the error is venial in its nature, and utterly insignificant in its effects. As I am conscious that it arose chiefly from my desire (shown in other ways and places) to do justice to our American fellow-workers in science, I am in no way ashamed of it; and I conceive that Prof. Newcomb should have been the last to comment in the manner he has done on the subject.

I shall not follow him in his discussion respecting irradiation, leaving Mr. Stone to deal, in his own good time, with the arguments by which two Continental astronomers (and one American mathematician) have sought to deprive him of his justly-earned credit.

I would submit, in conclusion, that February 1869 (the date of the presentation of the Astronomical Society's medal to Mr. Stone) can scarcely be described as "five years" ago even now, and my treatise on the sun was published in February 1871, Chapter I. being in type in November 1870. Nor has the council of the Astronomical Society (or any member of it) expressed any doubt, as yet, regarding the justice of the decision arrived at in 1869. Yet not a few members of the council have paid marked attention to Prof. Newcomb's attacks upon Mr. Stone. *Verbum sat.*

RICH. A. PROCTOR

Brighton, Nov. 24

The Density and Depth of the Solar Atmosphere

THE demonstration relating to the density and depth of the solar atmosphere, published in *NATURE* October 5, 1871, page 449, has been entirely misconceived by Mr. Ball. The volume of the terrestrial atmosphere is an element which obviously has nothing to do with the question. Atmospheric air, if raised to a temperature of $3,272,000^{\circ}$ Fah., will expand 6,443 times; hence a vertical column forty-two miles high will reach a height of

279,006 miles, if brought to the stated temperature. The basis of computation adopted by Captain Ericsson being an area of one square inch, he shows that a medium similar to the terrestrial atmosphere containing an equal quantity of matter for corresponding area, transferred to the solar surface, will, owing to the superior attraction of the sun's mass, exert a pressure of $14.7 \times 27.9 = 410$ pounds. And that, if the said medium be heated to a mean temperature of $3,272,000^{\circ}$ Fah., it will expand to a height of $279,006 = 10,000$ miles above the solar surface. But, if a gas

composed chiefly of hydrogen $1\frac{1}{4}$ times heavier than hydrogen the specific gravity of which is $\frac{1}{16}$ of that of air, be substituted, the height will be $\frac{14 \times 10,000}{16} = 100,000$ miles. Admitting

that the ascertained coefficient of expansion, 0.00203 for 1° Fah., holds good at the high temperature before referred to, the stated altitudes of the solar atmosphere cannot be disputed. Mr. Ball's announcement concerning the properties of spheres, it is scarcely necessary to observe, has no bearing on the foregoing calculations. With reference to the effect of intense heat, it will be well to bear in mind that the before-mentioned rate of expansion holds good for atmospheric air—within an insignificant fraction—under extreme rarefaction as well as under high temperatures. We have no valid reason, therefore, to suppose that any deviation from the ascertained law of expansion takes place in the solar atmosphere, sufficient to alter materially the before-mentioned computations of its depth.

Mr. Ball, in expressing the opinion that we shall not gain much correct knowledge of the solar atmosphere by the inquiry instituted by Captain Ericsson, forgets that the retardation which the radiant heat suffers in passing through our atmosphere has been ascertained, and that the properties of atmospheric air with reference to temperature and expansion are nearly identical with those of hydrogen, now admitted to be the chief constituent of the solar atmosphere. It is evident that Mr. Ball does not comprehend the object of adopting the terrestrial atmosphere as a means of determining the extent and depth of the solar atmosphere, since he does not perceive that the comparison instituted by Captain Ericsson has brought out the fact that either the depth of the sun's atmosphere exceeds 100,000 miles, or it contains less gaseous matter than the earth's atmosphere for equal area. The importance of this conclusion with regard to the determination of the retardation of the radiant heat in passing through the sun's atmosphere is self-evident to all who regard solar radiation as energy which cannot be absorbed unless an adequate amount of matter be present. Mr. Ball's suggestion that the retardation depends on the "chemical, i.e. molecular-constitution" of the solar atmosphere, calls to mind how libly some physicists talk of "arresting" one half, or more, of the solar energy. These reasoners apparently do not perceive that the means of arresting such stupendous energy is more difficult to conceive than the means of producing it.

Respecting the experiments which have been made with incandescent cast-iron spheres, and inclined discs, it is important to mention that previous experiments had established the fact that the radiant heat of flames transmits equal temperature, under similar conditions, as incandescent cast iron. The inference, therefore, which has been drawn by Captain Ericsson from the results of his experiments with incandescent cast-iron spheres regarding the feebleness of radiant heat emanating from the sun's border is not unwarrantable as supposed by Mr. Ball.

New York, Nov. 10

THULE

An Aberrant Foraminifer

I CHANCED upon an aberrant form of Peneroplis the other day, in which the free terminal series of chambers of this Foraminifer, ordinarily single, is constricted into two distinct tubes.

Though new to me, it may not be so to some of your readers; Dr. Carpenter, however, does not mention it in his monograph.

St. John's College, Cambridge

W. JOHNSON SOLLIAS

"New Original Observation"

ERNST FRIEDINGER, of Vienna, begins a communication on the subject of "which cells in the gastric glands secrete the

pepsine?"* as follows:—"Kölliker erwähnt zuerst das Vorkommen von zweierlei Zellen in den Pepsindrüsen des Hundes." "On referring to Kölliker I find, "Bei Thieren sind, wie Todd-Bowman zuerst beim Hunde, *ich* und Donders bei vielen andern Säugern gezeigt haben, die Magendrüsen überall doppelter Art," &c. In Todd and Bowman, published some years before this, the two kinds of glands are figured (the drawings being better than those of Kölliker), the difference between them in anatomical characters, the difference of the two parts of the gland, and the difference in the function discharged by the two kinds of cells of each of the two kinds of glands, pointed out. Friedinger does not even mention the names of the English observers. L. S. B.

New Zealand Forest-Trees

In your paper of Nov. 9 I observed a letter about New Zealand Forest-Trees, signed by Mr. John R. Jackson of Kew.

Mr. Jackson refers to several of the magnificent varieties of forest trees belonging to the natural order of Coniferae, which are widely distributed in New Zealand; omitting, however, some of the most common and most valuable, especially the Kahikatea or "white pine" of the settlers. This tree affords timber of a white colour, much like yellow deal in appearance and quality, which is admirably adapted for use as weather-board, flooring-boards, and scantling for all in-door work as well as for ordinary furniture. It is most extensively used for all those purposes. The "Totara" is particularly used for making shingles, which form a good substitute for slates as a covering for roofs.

The Rimu is used for such work as requires a more durable wood, and for the making of superior furniture, the wood being much harder and more difficult to work, than that of the Kahikatea, while its beautiful colour renders it very suitable for ordinary cabinet work.

Varieties of the acacia, called Kowai by the natives, supply timber which is specially adapted for the making of pales and fencing, and which is as durable as English oak; and there are many varieties of trees suitable for all purposes.

It is, however, in reference to that which is mentioned as the "Makia" that I think it worth while to trouble you, as I believe that I may be able to suggest what the word so referred to really is. I know of no tree or shrub so called, but Manuka, pronounced Manooka, is the name of the tree from which the natives in former times used to make all sorts of implements, especially the spears, which formed at once the weapons and the sceptres of the chiefs. That hardly deserves to be called a forest-tree, as it rarely attains any great size.

It belongs, I believe, to the family of "Diosma," and its wood is used to make axe-handles, ramrods for guns, &c. The leaves have a pleasant aromatic colour, and an infusion of them forms a passable substitute for tea, to which we were frequently glad to resort in the early times of New Zealand settlements. The fresh twigs form an elastic couch, which constituted our favourite bed on exploring parties and in temporary dwellings.

WILLIAM DAVISON

The Food of Plants

YOUR reviewer takes exception to my empirical description of carbonic acid in "Notes on the Food of Plants," p. 23. I readily admit—and I should have thought it was unnecessary to do so—that to describe carbonic acid as "carbon dioxide combined with water" is not *strictly* correct; but I think it is much more likely that I should have led my unscientific readers astray, had I explained, in more accurate language, the supposed composition of this acid.

CUTHBERT C. GRUNDY

The Germ Theory of Disease

IN NATURE, October 5, p. 450, Prof. Bastian, *versus* the Germ Theory, says:—"Such germs when present would be sure to go on increasing until they brought about the death of their host." Now, is it not well known that the larvæ of *Trichina spiralis* become encysted in the muscles of the animal infested by them, and are then perfectly harmless to their host, the fever, sometimes with fatal results, being produced by the

* Aus dem Ixiv. Bande der Sitzb. der k. Akad. der Wissensch. II. Abth. Oct.-Heft. Jahrg. 1871.

migration of the parasites from the alimentary canal through the tissues to their favourite muscles.

It is necessary, for the support of the germ theory, that the organism must be found in the blood?

GEORGE DAWSON

Balbriggan, Ireland, Nov. 20

The Origin of Species

SOME months since a letter appeared in NATURE, asking the author of the article on "The Origin of Species," published in the *North British Review*, 1867, to explain the following passage which occurs in the article:—"A million creatures are born; ten thousand survive to produce offspring. One of the million has twice as good a chance as any other of surviving, but the chances are *fifty to one* against the gifted individuals being one of the *hundred* survivors." There is an error in this passage; the word "hundred" should be altered to "ten thousand." I presume that with this correction the writer of the letter will have no difficulty in following the argument. I am much obliged to him for drawing my attention to the slip.

THE AUTHOR OF THE ARTICLE

NEW VOLCANO IN THE PHILIPPINES

THE island of Camiguin is situated to the north of Mindanao, at some six or eight miles from the coast, is only a few miles in circumference, and consists principally of high land. On the slopes and in the valleys is grown a large quantity of one of the most important staples of the Archipelago, the well-known Manila Hemp—the fibre of the *Musa textilis*.

On the first of May, 1871, after a series of violent earthquakes, a volcano burst out in a valley near the sea. The earth is said to have swelled, cracked, and then opened, ejecting large quantities of stones, sand, and ashes, but no liquid lava. The mischief done by the eruption was limited to a small area of two or three miles in extent, and the loss of life did not exceed eighty or ninety persons, who might have escaped if they had been less anxious to save their little property.

As the eruption and volcanic disturbances continued for some time, the alarmed natives abandoned the island in great numbers, and took refuge in the neighbouring islands of Mindanao, Bohol, &c., from which, after some weeks, the eruption having subsided, most of them returned. During the month of June the volcano ejected smoke and scoria, which latter are said to have been slowly pushed up as it were out of the crater, sliding down the sides over an underlying mass of fine grey ashes which were thrown out in the first instance; and a feeble action has continued by the latest accounts (August).

The eruption, instead of bursting from the top or sides of the higher hills, occurred in a valley between two spurs of high land near the sea and in the immediate neighbourhood of one of the principal villages, which the inhabitants abandoned, and do not seem disposed to re-occupy, though the damage done there was trifling.

As is usual here, the stories circulated were of the most exaggerated kind, and it is only by sifting and comparing the accounts of reliable eye-witnesses that I have been able to write an account at all worthy of attention. The observations made by two intelligent persons, who visited the island expressly for the purpose, have furnished the materials for this memorandum. The accounts as to the height of the cone are mere guesses—from 300 to 1,500 feet. H.M. surveying steamer *Nassau*, Captain Chimmo, is said to have visited the island in June, and we may therefore hope for a careful and scientific account of this phenomenon.

The present year has been remarkable for the extent and frequency of earthquakes over the whole of the Archipelago, though, with the exception of the case of Camiguin, they were not followed by any very serious consequences.

Manila, Sept. 25

WM. W. WOOD

SPECTROSCOPIC NOTES*

On the Construction, Arrangement, and best Proportions of the Instrument with reference to its efficiency.

THE spectroscope consists essentially of three parts—a prism, or train of prisms, to disperse the light; a collimator, as it is called, whose office is to throw upon the prisms a beam of parallel rays coming from a narrow slit; and a telescope for viewing the spectrum formed by the prisms.

Supposing the slit to be illuminated by strictly homogeneous light, the rays proceeding from it are first rendered parallel by the object-glass of the collimator, are then deflected by the prisms and finally received upon the object-glass of the view-telescope, which, if the focal lengths of the collimator and telescope object-glasses are the same, forms at the focus a real image of the slit, its precise counterpart in every respect except that it is somewhat weakened by loss of light and slightly curved.†

If the focal length of the view-telescope is greater or less than that of the collimator, the size of the image is proportionally increased or diminished.

This image is viewed and magnified by the eye-piece of the telescope.

If now the light with which the slit is illuminated be composite, each kind of rays of different refrangibility will be differently reflected by the prisms, and form in the focus of the telescope its own image of the slit. The series of these images ranged side by side in the order of their colour constitutes the spectrum, which can be perfectly pure only when the slit is infinitely narrow (so that the successive images may not overlap), and accurately in the focus of the object-glass of the collimator, which object-glass, as well as that of the telescope, must be without aberration either chromatic or spherical, and the prisms must be perfectly homogeneous and their surfaces truly plane.

Of course, none of the conditions can be strictly fulfilled. An infinitely narrow slit would give only an infinitely faint spectrum; and no prisms or object-glasses are absolutely free from faults. A reasonably close approximation to the necessary conditions can, however, be obtained by careful workmanship and adjustment, and it becomes an important subject of inquiry how to adapt the different parts of the instrument to each other so as to secure the best effect, and how to test separately their excellence, in order to trace and remedy as far as possible all faults of performance.

With reference to the battery of prisms, several questions at once suggest themselves relative to the best angle and material, the number to be used, the methods of testing their surfaces and homogeneity, and the most effective manner of arranging them.

Angle and Material of the Prisms.—As to the refracting angle, the careful investigation of Prof. Pickering, published in the *American Journal of Science and Art* for May 1868, puts it beyond question that with the glass ordinarily employed an angle of about 60° is the best. For instruments of many prisms there is an advantage as regards the amount of light in making the angle such that the transmitted ray at each surface shall be exactly perpendicular to the reflected. For ordinary glass, the refracting angle determined by this condition somewhat exceeds 60° ; for the so-called "extra-dense" flint it is a little less.

The high dispersive power of this "extra-dense" glass is certainly a great recommendation. But it is very yellow, powerfully absorbing the rays belonging to the upper portion of the spectrum, and is very seldom homogeneous. It is so soft also, and so liable to scratch and tarnish, that it can only be safely used by casing it with some harder and more permanent glass, as in the compound prisms of Mr. Grubb, and the direct vision prisms of many makers.

For many purposes these direct vision prisms are very convenient and useful, but they are hardly admissible in instruments of high dispersive power designed to secure accurate definition of the whole spectrum, the violet as well as the yellow.

* By C. A. Young, Ph.D., Professor of Natural Philosophy and Astronomy in Dartmouth College. Reprinted from advance-sheets of the *Journal of the Franklin Institute*, by permission of the Editor.

† The curvature arises from the fact that the rays from the extremities of the slit, though nearly parallel to each other, make an appreciable angle with those which come from the centre. They therefore strike the surface of the prisms under different conditions from the central rays, and are differently refracted, usually more. The higher the dispersive power of the instrument and the shorter the focal length of the collimator, the greater this distortion, which is also accompanied by a slight indistinctness at the edges of the spectrum.

Test for Flatness of Surface.—For testing the flatness of the prism surfaces, probably the best method is to focus a small telescope carefully upon some distant object (by preference the moon or some bright star), and then to scrutinise the image of the same object formed by reflection from the surface to be tested. Any general convexity or concavity will be indicated by a corresponding change of focus required in the telescope; any irregularity of form will produce indistinctness, and by using a cardboard screen perforated with a small orifice of perhaps $\frac{1}{4}$ inch in diameter, the surface can be examined little by little, and the faulty spot precisely determined.

Test for Homogeneity.—It is not quite so easy to test the homogeneity of the glass. Any strong veins may, of course, be seen by holding the prism in the light, and if the ends of the prism are polished, the test by polarised light will be found very effective in bringing out any irregularities of density and elasticity in the glass. A blackened plate of window glass serves as the polariser; a Nicol's prism is held in one hand before the eye in such a position as to cut off the reflected ray, and with the other hand the glass to be tried is held between the Nicol and the polariser. If perfectly good it produces no effect whatever; if not it will show more or less light, usually in streaks and patches.

On the whole, however, the method of testing which has been found most delicate and satisfactory is the following:—

A Geissler tube containing rarefied hydrogen is set up vertically, and illuminated by a small induction coil.

A small and very perfect telescope of about six inches focus is directed upon it from a distance of seventy-five or one hundred feet, and carefully adjusted for distinct vision.

The prism to be tested is then placed in front of the object-glass of the telescope with its refracting edge vertical, adjusted approximately to the position of minimum deviation, and telescope and prism together then turned (by moving the table on which they stand), until the spectrum of the tube appears in the field of view. This spectrum consists mainly, as is well known, of three well-defined images of the tube, of which the red image, corresponding to the C line, is the brightest and best defined, and stands out upon a nearly black background.

Supposing then the flatness of the prism surfaces to have been previously tested and approved, the goodness of the glass may be judged of by the appearance and behaviour of this red image; and by using a perforated screen in the manner before described, inequalities of optical density are easily detected and located. Irregularities, which would hardly be worth noticing in a telescope object-glass, where the total deviation produced by the refraction of the rays is so small, are fatal to definition in a spectroscope, especially one of many prisms, and it is very difficult to find glass which will bear the above-named test without flinching. Of course it must be conducted at night, or in a darkened room.

Number and Arrangement of Prisms.—The number of prisms to be employed will depend upon circumstances. If the spectrum to be examined be faint, and either continuous or marked with dark lines, or by diffuse bands, either bright or dark, we are limited to a train of few prisms.

The light of the sun is so brilliant that, in studying its spectrum, we may use as many as we please. The light is abundant after passing through 13, and I presume would still be so if the train were doubled.

Spectra of fine well-defined bright lines also bear a surprising number of prisms. The loss of light arising from the transmission through many surfaces is nearly, if not quite, counterbalanced by the increased blackness of the background, and the greater width of slit which can be used.

As to the best arrangement for the prisms, this also must be determined by circumstances.

Where exact measurements are aimed at, as, for instance, for the purpose of ascertaining the wave-length of lines, or the dispersion co-efficient of a transparent medium, the prism or prisms ought to be firmly secured in a positive and determinable relation to the collimator. A train of many prisms can hardly be safely used in such work on account of the difficulty in obtaining this necessary fixity, and if high dispersion is indispensable, it can only be obtained by enlarging the apparatus.

But for most purposes it is better that the prisms, instead of being fixed, should be mounted upon some plan which will secure their automatic adjustment to the position of minimum deviation.

Having now thoroughly tried the plan which I proposed and

published in this Journal last November, I am prepared to say that I cannot imagine anything more effective and convenient.

The arrangement of Mr. Browning and its extension by Mr. Proctor, are equally effective so far as the adjustment of the prisms is concerned, but are less compact and simple, and do not afford the same facility in changing the number of prisms in use.

In my instrument the light, after leaving the collimator, falls perpendicularly upon the face of a half-prism, passes through the train

of prisms near their bases; at the end of the train is twice totally reflected by a rectangular prism attached to the last of the train (which is also a half prism), is thus transferred to the upper story of the train, so to speak, and returns to the view-telescope, which is firmly attached to the same mounting as the collimator and directly above it. Both are immovable, and the different portions of the spectrum are brought into view by means of the screw, which acts upon the last prism, and through it upon the whole train. The adjustment for focus is by a milled head, which carries the object-glasses of both collimator and telescope in or out together. Since they have the same focal length, this secures the accurate parallelism of the rays as they traverse the prisms.

The annexed diagram, taken from the paper already alluded to,* exhibits the plan of the arrangement, and requires no explanation, unless to add that, to avoid complication in the figure, I have represented only two of the radial forks which maintain the prisms in adjustment; also, that the prisms are connected to each other at top and bottom, not by hinges, but by flat springs, preventing all shake.

By adding another tier of prisms and sending the light back and forth through a third and fourth story, the dispersion can be easily doubled with very small additional expense, except for the prisms themselves; the mechanical arrangements remaining precisely the same.

I desire, in this connection, to call attention to the great ad-

vantages gained by the use of the half prism at the commencement of the train, a point which hitherto seems to have escaped notice.

With a prism of 60° , having a mean refractive index, μ , 1.6, and placed in its best position, the course of the rays is as shown in Fig. 2. The side ab is just $1\frac{1}{2}$ times the cross section, a, d ,

* After the appearance of the article referred to, I found that Mr. Lockyer had anticipated me by some months, not only in respect to the method of making the rays traverse the prism train twice, but also in the use of a half prism at the beginning of the train, and the employment of an elastic spring in the adjustment for minimum deviation. In all essential particulars his instrument is the same as mine, though in some matters of detail there are differences which have proved to be of practical importance in favour of my own.

Mr. Lockyer has, however, never printed an account of his instrument, and at the time of my publication I knew only the fact (which I then mentioned), that he intended to send the light twice through the prism train by a total reflection.

The beautiful instrument recently constructed for Dr. Huggins by Mr. Grubb differs mainly in using compound prisms, and in producing the adjustment for minimum deviation by an arrangement of link work, which, though not theoretically exact, is practically accurate.

of the transmitted beam. In other words a prism of the same material and angle described, in order to transmit a beam one inch in diameter, must be one inch high and have sides $1\frac{1}{2}$ inches long.

But when the light is received perpendicularly upon the face of a half prism, as in Fig. 3, then, since $bc = be \div \cos 30^\circ$, the length of the prism side, bc , requires to be only 1.155 times as great as the diameter of the transmitted beam.

Thus a train of prisms each 1 inch high, and having the sides of their triangular bases each 1.155 inches long, led by an initial half prism in the way indicated, would transmit a beam 1 inch in diameter, while without the initial half prism the sides would

have to be 1.667 long, the surface to be worked and polished would be 1.44 (*i.e.* $1.667 \div 1.155$) times as great, and the quantity of glass required 2.08 (*i.e.* 1.44^2) times as great. With a higher index of refraction the gain is still greater.

This advantage of course is not obtained without losing the dispersive power of one half prism. But where the train is extensive this loss is comparatively insignificant, and may be made up by a slight increase of the refracting angles. Indeed, in an instrument of the form above described, it is necessary, if the train is led by a whole prism, to reduce the refracting angle from 60° to about 55° , in order that the reflecting prism at the end of the train may not interfere with the collimator, while with the initial half prism the full angle of 60° can be used, so that in this case there is practically no loss whatever.

It would seem to deserve consideration, whether in the construction of spectroscopes to be used with some of the huge telescopes now building, it may not be advisable to carry the principle still further, by employing two or more half prisms at the beginning of the train in order to economise material and weight.

Dispersive Efficiency.—The dispersive efficiency of the spectroscopic is its ability to separate and distinguish spectral lines whose indices of refraction differ but slightly; it is closely analogous to the *dividing power* of a telescope in dealing with double stars. It depends* not only upon the train of prisms, but also upon the focal lengths of the telescope and collimator, the width of the slit, and the magnifying power of the eye-piece.

As has been said before, each bright line is an image of the

slit whose magnitude, referred to the limit of distinct vision, depends upon the telescope and collimator, but is independent of the prism train. The distance between the centres of two neighbouring lines, on the other hand, depends upon the number and character of the prisms, the focal length of the telescope, and the magnifying power of its eye-piece, but is totally independent of the collimator.

In order that two lines may be divided, it is necessary that the edges of their spectral images should be separated by a certain small distance—a *minimum visible*, whose precise value is of no particular importance to our present purpose, but which I suppose to be about $\frac{1}{100}$ of an inch.

* It is very common to describe the dispersive power of a spectroscopic as being equivalent to a certain number of prisms, or a certain number of degrees from A to H. But either method fails entirely to convey an idea of the appearance of the spectrum in the instrument, and it is much better to name the closest double line which it will divide, or else to give the distance between the two D lines, either linear (referred of course to the limit of distinct vision), or angular. If we know, for example, that the D lines are separated $1''$, or, what comes to the same thing, appear to be one-sixth of an inch apart, we have a definite idea of the power of the instrument.

From these principles it is easy to deduce a formula which will express the dispersive efficiency of a given instrument, and enable us to judge of the effect of variations in the proportion and arrangement of the parts.

Let f be the focal length of the collimator.

- f^1 " " " " telescope.
 m the magnifying power of the eye piece (which is found by dividing the limit of distinct vision by the equivalent focal length of the eye-piece and adding unity to the quotient).
 n the number of prisms in the train.
 w the width of the slit.
 h the minimum visible above alluded to.
 $d\mu$, the difference between the indices of refraction for two adjacent lines; and finally
 δ , the co-efficient of dispersion for each prism (which, r being the refracting angle of the prism, is given by the equation

$$\delta = \frac{\sin \frac{1}{2} r}{1 - \mu^2 \sin^2 \frac{1}{2} r}$$

If, now, we put D for the distance between the centres of the two lines, and b for their breadth, we shall have

$$D = m n \delta f^1, d\mu, \text{ and } b = m w f^1 \div f.$$

But the distance between the edges of the lines equals $D - b$; and this, for two lines as close as the instrument will divide, must equal h .

Hence $k = m n \delta f^1, d\mu - \frac{m w f^1}{f}$. Finding from this the value of $d\mu$, taking its reciprocal as a measure of the dispersive efficiency of the instrument, and calling it E , we get

$$E = m n \delta \frac{f^1}{k f + m w f^1} \quad (1)$$

This formula, in which m , n , and δ appear as simple factors, of course supposes that the perfection of workmanship and intensity of the light are such that there is no limit to the magnifying power and number of prisms which may be employed.

My special object, however, in working it out has been to exhibit clearly what is evident from its last term, the dependence of the dispersive efficiency upon the focal lengths of collimator and telescope.

Differentiating equation (1) with respect to f and f^1 , we obtain

$$dE = m, n, \delta \left\{ \frac{k f^2 (d f^1) + m w f^1 (d f)}{(k f + m w f^1)^2} \right\} \quad (2)$$

which shows that any increase in either f or f^1 adds to the dispersion. If f increases, both D and b increase in the same proportion, and so, of course, does the width of the interval between the adjacent lines; while every augmentation of f^1 decreases the width of the spectral images without in the least affecting the distance between their centres.

This principle seems to have been often overlooked, and collimators and telescopes of short focus employed when longer ones would have been far better.

In spectroscopes designed to be used for astronomical purposes, at the principal focus of a telescope, there is, of course, no advantage in making the angle of aperture of the collimator much greater than that of the equatorial itself; accordingly a collimator of one inch aperture ought to have a focal length of 10 or 12 inches, or, if special reasons determine a focal length of only 6 inches, then it is needless to make the collimator and view telescope much over half an inch in diameter, and the prisms may be correspondingly small.

If, on the other hand, the focus of telescope or collimator is lengthened for the purpose of securing increased dispersion, object glasses and prisms must also be correspondingly enlarged, in order to transmit the same amount of light.

It is, perhaps, worth noting that when f and f^1 are equal, formula (1) becomes simply

$$E = \frac{m, n, \delta, f}{k + m w} \quad (3)$$

Luminous Efficiency.—The extreme faintness of many spectra greatly embarrasses their study, so that it becomes a matter of interest to examine how the different dimensions and proportions of a given instrument stand related to the brightness of the spectrum produced.

It appears to be necessary, for this purpose, to distinguish two

classes of spectra, those composed of narrow and well defined bright lines, and those which are not, the light being spread out more or less evenly and continuously.

The brightness of a spectrum of the latter kind is evidently directly proportional to the amount of light admitted, diminished by its subsequent losses, and inversely to the area over which it is distributed; similar considerations apply in the first case, only as the lines are exceedingly narrow images of the slit, their brightness, being independent of their distance from each other, is inversely proportional to the length of the lines simply—i.e., to the width of the spectrum, having nothing to do with its length.

Using the same notation as before, merely adding

i = intensity of source of light.

l = length of the slit.

a = linear aperture of the collimator object glass;

and supposing the prisms and view telescope of a size to take in the whole beam transmitted by the collimator, and that the angular magnitude of the luminous object, as seen from the slit, is sufficient to furnish a pencil large enough to fill the collimator object glass, we shall then have for the quantity of light transmitted to the prisms the expression

$$i l w \frac{a^2}{f^2}.$$

This is afterwards diminished in passing through the prism train and telescope.

To estimate the precise amount of this loss is very difficult, and the algebraic expression for it is of so complicated a character that it would be of little use to attempt to introduce it into our formula. Calling it S , however (which of course is a function of the number and refracting angle of the prisms, as well as of the optical character of the glass), we may write for the quantity of light effective in forming the spectrum,

$$Q = i l w \frac{a^2}{f^2} - S. \text{ And this expression applies to both kinds}$$

of spectra—bright line and continuous.

In the continuous spectrum this light is spread out over an area whose length is the angular dispersion of the train Δ , multiplied by the magnifying power of the eye-piece and by the focal length of the view telescope, and whose breadth is the width of the spectrum. Putting A for this area, we have

$$A = \frac{l m^2 n \Delta \cdot f^1^2}{f}.$$

And for the intensity of light in the continuous spectrum, which equals $Q \div A$, we get finally

$$L = \frac{i l w a^2 - f^2 S}{l m^2 n \Delta f^1^2 f} \quad (4)$$

If we neglect the loss of light in transmission, and take $f = f^1$, the formula simplifies itself to

$$L = \frac{i w a^2}{m^2 n \Delta f^3} \quad (5)$$

Either of these formulae shows how rapidly the light is cut down by any increase of the dispersive power, whether by adding to the prism train or by enlargement of the linear dimensions of the apparatus.

Our only resource in dealing with spectra of this kind, when the limit of visibility on account of faintness is nearly attained, seems to be either to increase i or a . If the luminous object be a point (like a star) we can do the former by concentrating its light on the slit with a lens; if it be diffuse, like the light of the sky, I know no means for producing the desired concentration, and we can only gain our end by increasing the angular aperture of the collimator.

For the discontinuous bright-line spectrum, the case is quite different. Q , i.e., the quantity of light which goes to form the spectrum, remains unchanged, but instead of A the whole area covered by the spectrum we have only to consider its width, i.e., the length of the lines.*

* $\Delta = n \left(\sin^{-1} (\mu_n \times \sin \frac{1}{2} r) - \sin^{-1} (\mu_h \sin \frac{1}{2} r) \right)$ where μ_n and μ_h are respectively the indices of refraction for the lines A and H; the prisms being supposed to be so mounted as to maintain the position of minimum deviation.

† So long as the opening of the slit is small enough to secure accurate definition of the lines, it is not necessary to take into account either this or the magnifying power as diminishing the brightness of the lines by increasing their breadth, since irradiation alone gives them a sensible width sufficient to render the effect of other causes comparatively unimportant.

We then have $A^1 = \frac{lmf^1}{f}$;

and for the brilliance of the bright line spectrum, we get

$$\Lambda = \frac{Q}{A'} = \frac{i l w a^2 - f^2 S}{l m f f^1} \quad (6)$$

If we neglect S , the loss of light in transmission through the apparatus, and suppose $f = f^1$, this becomes

$$\Lambda' = \frac{i w a}{m f^2} \quad (7)$$

These formulæ show that with a spectrum of this kind we may, without diminishing the brightness of the lines, increase the dispersive power of our instrument to any extent by increasing its linear dimensions; if we increase the dispersive power by adding to the prism train, the case is different, since S is a function of n , the number of prisms.

New form of Spectroscope.—I close the article with the suggestion of a new form for a chemical spectroscope, which seems to present some advantages in the saving of material and labour as well as of light.

The figure (Fig. 4) sufficiently illustrates it, except that it may be necessary to add that I have not represented any of the many possible convenient arrangements for reading off the positions of lines observed. The centre of motion for the telescope is at c , the collimator remaining fixed.

The half prisms of heavy flint-glass are concave at the rear surface, and directly cemented to the single crown glass lenses, which form the object-glasses of telescope and collimator. There is thus a saving of two surfaces over the common form; and, what is more important, the prisms to fit telescopes of a given aperture are considerably smaller on the face, and can be made from plates of glass of less than half the thickness required by the ordinary construction, a circumstance which greatly reduces the difficulty of obtaining suitable material.

NOTES

WE learn by British-Indian cable that the English Government Eclipse Expedition arrived at Galle on Monday last; all well. The authorities in India and in Ceylon are doing everything they can to assist the party. M. Janssen has gone to the Neilgherries. Mr. Lockyer is in communication with Colonel Tennant. The weather was at that time fine.

PROFESSOR JOHN YOUNG has written to the *North British Daily Mail*, detailing the reasons for the notice of motion which he gave in April last to the General Council of the University of Glasgow, relative to the division of the chair of Natural History with that University. The duties of the chair would render it incumbent on its occupant to teach, if required to do so, Zoology, Comparative Anatomy and Physiology, Geology and Palæontology, Mineralogy, Mining, Metallurgy, and possibly Meteorology. Actually, Professor Young gives instruction in Comparative Anatomy and Geology. He is naturally extremely anxious that he should no longer be called upon to teach subjects which, in the present state of science, it is impossible to be efficiently combined. It is to be hoped that, before long, the University will see the necessity of instituting a separate chair of Geology, as has recently been done at Edinburgh; but where will be found a Sir Roderick Murchison to endow it in so munificent a manner?

AT the second M.B. Examination for Honours at the University of London, Mr. William Henry Allchin, of University College, has taken the Scholarship and gold medal, and Mr. Henry Edward Southey, of Guy's Hospital, the gold medal in Medicine; Mr. Richard Clement Lucas, of Guy's Hospital, the gold medal in Obstetric Medicine, and Mr. Ernest Alfred Elkington, of the General Hospital, Birmingham, the gold medal in Forensic Medicine. At the second B.A. and second B.Sc. Examination, Mr. Thomas Oliver Harding, of Trinity College, Cambridge, obtained the Scholarship in Mathematics and Natural Philo-

sophy. No gold medals were awarded in Animal Physiology, Chemistry, Geology and Palæontology, or Zoology.

MR. LAZARUS FLETCHER, of the Manchester Grammar School, was on Saturday last elected to the vacant scholarship at Balliol College, on the foundation of Miss H. Brakenbury, for the encouragement of the study of Natural Science. Mr. Hainsworth, of the same school, and Mr. Greswell, of Louth School, were also mentioned by the examiners as worthy of commendation. The scholarship is worth 70*l.* a year, and is tenable for three years.

WITH reference to the destruction of the Museum at Chicago, we learn that Dr. Stimpson's own collection of North American shells formed part of the Smithsonian Museum; and that the collection made by Professor Agassiz and Count Pourtales, in their deep-sea explorations of the Gulf of Mexico, belonged to the Cambridge Museum. Many of Dr. Stimpson's MSS. and drawings have been published. Mr. Gwyn Jeffreys was, as our readers are aware, fortunately the means of saving some of the shells from the Gulf of Mexico, which he is now engaged in working out before returning. Many valuable specimens which Mr. Jeffreys took to Chicago of course shared the fate of the remainder; some of them, however, he hopes to be able to replace. Professor Agassiz has offered Dr. Stimpson a place at Cambridge, Mass., and to give him the means of again carrying on dredging operations in the Gulf of Mexico.

A FINE young pair of the Grey seal (*Halichoerus grypus*) has just been added to the Zoological Society's living collection. This species, although not uncommon on some parts of the British coast, has never previously been received alive by the Society. The present specimens were obtained near St. David's in South Wales, where this seal is said to be of not unfrequent occurrence. Besides this seal, the Society's collection also contains examples of three other Phocids—namely, the sea-lion (*Otaria jubata*), the Cape eared seal (*Otaria pusilla*), and the common seal (*Phoca vitulina*).

IN the Northern United States the richest marine fauna is to be found in the vicinity of Eastport, Maine, the adjacent region of the Bay of Fundy having become classic ground through the labours of Stimpson, Verrill, Packard, Morse, Webster, Hyatt, &c. It is rumoured, according to *Harper's Weekly*, that Mr. J. E. Gavit, of New York, president of the American Bank-note Company, and at the same time an eminent microscopist, has it in contemplation with some friends to erect a building at Eastport, to be suitably endowed and maintained for the use of any naturalists who may wish to avail themselves of the facilities it may afford. We can only hope that so excellent an idea may be realised at an early day.

THE latest advices from Captain Hall's expedition were dated at Upernavik, September 5, being somewhat later than the information brought back by the *Congress*. After parting with the *Congress* at Disco, Captain Hall sailed nearly north until he reached the harbour of Proven, where he landed and endeavoured to obtain dogs. In this, however, he was not very successful, procuring only eighteen, most of which were not well fitted for service. From Proven the *Polaris* proceeded to Upernavik, arriving there on the 30th of August. He left that port on the 5th of September, and continued on his polar journey.

AMONG the movements of naturalists abroad, we understand that Mr. J. Matthew Jones, F.L.S., President of the Nova Scotian Institute of Natural Science, intends spending the winter months in the Bermudas, for the purpose of more thoroughly investigating the marine zoology of the group.

MESSRS. WESTERMANN, of Brunswick, announce for early

publication, in two volumes, a rendering into German, by Herr Schellen, of the French translation of P. Secchi's "Le Soleil."

THE *Feuille des Jeunes Naturalistes*, to which we called attention some time ago, has entered on its second year of existence in a somewhat enlarged form. Aiming at the development of an intelligent love of nature amongst French schoolboys, it claims the sympathy of all those amongst ourselves who, by means of school museums and natural history societies, are labouring in the same field. The editor solicits contributions from English boys, on any subject connected with natural science, which he promises carefully to translate and publish.

ON the 5th of January, 1872, will be published, in Bombay the first number of a monthly journal, the *Indian Antiquary*, intended as a medium of communication between Oriental scholars in India, Europe, and America, and a repository for information on the Antiquities, History, Geography, Literature, Religion, Mythology, Natural History, Ethnography, and Folk-lore of India and adjoining countries, and thus embracing a similar variety of subjects to the English *Notes and Queries*, the plan of which the *Indian Antiquary* will, to some extent, follow. The most eminent Orientalists in India, Europe, and America, it is expected, will become contributors to the pages of this journal, and it will be edited by Mr. J. Burgess, M.R.A.S., F.R.G.S. The London agents will be Messrs. Trübner and Co.

WE have received the first number of "The Garden," a weekly newspaper, edited by Mr. W. Robinson, F.L.S. It contains original articles by the editor and other correspondents on gardening topics, illustrated by wood-cuts, instructions for gardeners suited to the time of the year, descriptions of new plants, &c.

MR. W. F. DENNING, the Honorary Secretary of the Observing Astronomical Society, publishes "Astronomical Phenomena in 1872," a complete guide to the astronomer for the more important phenomena to be looked for during the year.

MR. ROTHSCHILD, of the Rue des Saints Pères, Paris, has commenced publishing, in large folio numbers, a magnificent work upon the Trajan Column at Rome. A complete series of mouldings was executed in 1862, by order of the Emperor, for the Louvre Museum. A cast was taken of these mouldings in galvano, by the Procédé Oudry, and from these casts phototypographic plates have been done. There will also be many wood-cuts interspersed through the work. The letterpress will be by M. W. Frochner, the conservator of the Louvre Museum. It will be finished in 1873.

MR. CUTHBERT COLLINGWOOD, M.A. and B.M., Oxon, F.L.S., &c., author of "Rambles of a Naturalist on the Shores and Waters of the China Seas," &c., announces, as in the press, "A Vision of Creation," a poem, with an introduction, geological, and critical.

PROF. HUXLEY, in his address at the distribution of prizes at the Oxford Local Examination at Manchester, spoke as follows: "He believed that he was speaking entirely within measure when he said now that there was nowhere in the world a more efficient or better school, so far as it went, for teaching the great branches of physical science than was at the present time to be found in the University of Oxford. He thought it right that he should here state what had come to his knowledge as a member of the Royal Commission connected with these matters. That noble University had within the last ten or fifteen years devoted no less than about 100,000*l.* to the endowment and equipment of physical science and physical science only.

M. JOLY, a distinguished member of the French Academy of Medicine, has recently read a paper before that learned society, in which he attributes the enervation of the nation, as evinced

during the late war, to the combined effect of alcohol and nicotine upon the national character. "Tobacco," says Dr. Joly, "although of only recent introduction, has gained upon its older rival. Imitativeness and 'moral contagion' have done their work, until the use of this poison has penetrated everywhere—has enslaved the nation, caused personal and racial degeneracy, enervated the entire army, and made it slow to fight and powerless in action. The use both of spirits and tobacco has frightfully increased, and human depravity could scarcely devise a worse compound than the mixture of brandy and tobacco, which is the latest liquid novelty patronised by Parisian sensualists. The French consume more tobacco than any other nation."

THE *Gardener's Chronicle* states that a series of photographs devoted to the illustration of Linnean relics has been recently issued in Sweden, and copies are to be procured in London. They consist of photographs of Linné's statue in the Botanical Garden at Upsala, of the Botanical Garden itself, the monument in Upsala Cathedral, his country seat and museum at Hammarby, a portrait, one of his letters, and other objects of interest in connection with the great naturalist.

AN interesting contribution to the supposed "Serpent Worship" in Scotland is stated to have been lately discovered near the shores of Loch Fell, near Oban, where the form of a monstrous serpent three hundred feet in length has been disinterred. From the accounts which have been published it would appear that the figure of the serpent was excavated in the rocks above the lake, and had become overgrown.

SOME interesting experiments have lately been tried at the Crystal Palace to improve the illuminating power of ordinary gas. The inventor, by mixing a certain proportion of oxygen with the gas as it issues from the burner, claims to have found both a more economical and a more wholesome method of burning gas. There is no doubt that the light is much more brilliant, the only question is whether it is not too expensive. The oxygen is generated by passing supersaturated steam over red manganate of soda previously heated in dry air. The steam absorbs the oxygen from the manganate, and on being condensed the oxygen passes over alone and is mixed with the gas at the burner.

THE *Indian Medical Gazette* says that a report furnished by the Inspector of Police to the Bengal Government shows that of 939 cases of snake bites in which ammonia was administered by the police 702 are reported to have recovered, and the average length of time between the bite and the application of the ammonia is said to have been in fatal cases 4h. 12m. 13s., and in cases of recovery 3h. 28m. 14s.

ON the 29th of September a slight shock of earthquake was felt at Memoodabad in the Ahmedabad Collectorate, Bombay.

IT is stated that an aerolite weighing 127lb. fell lately near Montreux (Seine-et-Marne) in France. It appears to have come from the east, and burst with a loud explosion, giving a bright blue light. It is of an irregular spheroid shape and black, and is to be sent to the Academy of Sciences.

A VERY violent typhoon raged at Hongkong on the 2nd of September, doing an immense amount of damage both on land and sea.

ON October 16th a terrific hurricane swept over Halifax, New Brunswick, and caused a large amount of damage. It was accompanied by an extraordinary high tide, which was unexampled in the history of the city for damage and violence. On the same and the following day, very heavy storms were experienced on Lake Superior and Lake Huron, which caused the destruction of many vessels and the loss of numerous lives.

IN Ecuador there have been discovered in the forests of Santa Helena the trees yielding the red guinea bark.

AN earthquake took place in the beginning of October on the Isthmus of Chiriqui near Panama.

DR. ROBERT BROWN, in a communication on the "Interior of Greenland," states that all the results of the attempted explorations of the interior serve to show that this is one huge *mer de glace*, of which the outlets and overflow are the comparatively small glaciers on the coast, though when compared with the glacier system of the Alps, they are of gigantic size. The outskirting land is, to all intents and purposes, merely a circlet of islands of greater or less extent. There are, in all probability, no mountains in the interior—only a high plateau, from which the unbroken ice is shed on either side to the east and west, the greater slope being toward the west. No mountains have been seen in the interior, the prospect being generally bounded by a dim, icy horizon. Dr. Brown considers Greenland susceptible of being crossed from side to side with dog or other sledges, provided the party start under experienced guides, and sufficiently early in the year.

OCCASIONAL glimpses of pre-historic times are afforded to us. One of the Indian papers records the deeds of a mad elephant, which made its way from the Rewah territory into the Mundla district. The first day it attacked the village of Tarraj, when the inhabitants took refuge on the roofs, but it killed a woman and child. The next night it went to the village of Mauzah and killed a boy. Two days after it killed a woman at Barbashore, and on the following night added to the number a man and woman at Kamaria. Thence it made its way to Donoria, and the villagers tried to escape, but two old women met their death, and another was trampled on and seriously injured. Its next stage was Manori, destroying a woman and two children, and so to Karbah. Here it snatched a baby from the mother's arms and killed it, and in the evening succeeded in killing a man in the same place. The next night a man was killed at Nigheri, and on that following another at Banu. On the 7th February it met with a check in passing the Ramguruh Tahsil, where it was fired on, and retreated to Bijori, taking revenge by killing a man and a boy. On the 8th it surprised a party of villagers in the jungle, who had escaped from Nanda, again taking a woman's baby from her arms and killing it. The next slaughter was of a man at Belgaon and another at Belgara. It then visited Sayla, the villagers making their escape, except one boy, who was caught by it, but only rolled about for fun, but the elephant went into the village and pulled down several houses. By the 15th he was at Mohari, and injured a man and woman by rolling them about without killing them. On the 19th it killed one man and wounded another at Naraingunj. By this time a party was got together to resist it, about three weeks having elapsed, and the animal was driven across the river Nerbudda and into the jungle of a hill, but from which the force was inadequate to dislodge it. In three weeks it drove the people out of many villages, killing twenty-one persons, wounding others, and ravaging the country. It is alleged to have devoured five of its victims. The above recital of what took place in a relatively settled country, gives colour to the legends of Hercules and Theseus. In this case nothing is said of the destruction of crops which must have taken place.

AN improvement in the apparatus attached to fire-engines has been proposed by Mr. Prosser in the form of a spreading fire-nozzle, the object of which is, by means of a number of moveable as well as fixed fingers so to direct the jet of water that it shall divide it into a more or less fine spray. The water is thus economised, and instead of a large proportion running off after scarcely coming into contact with the burning material, every drop, falling in the form of a conical shower of rain, performs its part towards extinguishing the fire.

COLDING ON THE LAWS OF CURRENTS IN ORDINARY CONDUITS AND IN THE SEA

II.

FÖRCHHAMMER has filled up that gap by his researches upon the water of the ocean; for we can now, by the help of his results and of the temperatures, ascertain pretty exactly the specific weight of the water of the ocean in the principal seas of the globe. Calculation has proved the correctness of Maury's original notion, viz., that the density of the water of the ocean is least at the equator, and increases with tolerable regularity in proportion as we advance towards the north and towards the south. The water of the Atlantic seems to be of the greatest density at about 60° N. latitude to the south and south-east of Greenland. If we take this density as unity, the specific weight of the water of the sea will on an average be represented by the following numbers:—

NORTHERN HEMISPHERE	SOUTHERN HEMISPHERE
Between 60° and 70° latitude in Davis Straits	'09980 Unknown
About 60° latitude in the Atlantic	'09900 Unknown
Between 50° and 60° latitude in the Atlantic	'09984 In the Cold Currents of Cape Horn
Between 40° and 50° latitude in the Atlantic	'09995 In the Atlantic
Between 23° and 40° latitude in the Atlantic	'09972 In the Atlantic
Between 0° and 23° latitude in the Atlantic	'09966 In the Atlantic

Of these the former, those of the Northern Hemisphere, are most to be depended on, because the observations there have been most numerous.

It will be seen by this table that the density of the water of the ocean increases along with the latitude, and in almost the same proportion both north and south of the equator. But Förchhammer has also determined the saltness of the sea at various depths, and has found that it decreases in very slow proportion with the increase of the depth. If we start from this fact, taking account at the same time of the decrease of temperature in proportion to the depth, we find the result to be that, at 500 fathoms below the surface, the density of the water of the sea over the whole globe may be considered as equal to 1, the difference at any particular point being scarcely discernible. But since the density of the water of the ocean at a depth of 3,000 feet is everywhere equal to 1, and since at the surface it diminishes as we approach the equator, it is evident that the mass of water underneath cannot be in equilibrium; that if the surface of the sea is more elevated between the tropics than under the poles, and if we take the mean densities given above, at the surface, and at the bottom of this liquid mass, we find that the height of the surface of the sea above the level corresponding to the density of 1, ought to be nearly as follows:—

Height between the Equator and the Tropics 6° 6' lat.	
" " Tropics and 40° lat.	4' 2"
" " 40° and 50°	2' 2"
" " 50° and 60°	0' 9"
" " at 60°	0' 0"
" " between 60° and 70°	3' 0"

But a similar difference of level necessitates the formation of a double surface-current passing from the equator to the two poles, and that cannot take place without entailing a diminution of the height of the water under the tropics, unless, indeed, there be an equivalent afflux into the tropical seas. But if the level of the water between the tropics be lower, the equilibrium of the under strata will be destroyed, and there ought, consequently, to be a submarine current which comes both from the north and the south towards the equator. That there really exists a current in that direction is a result of the circumstance that the temperature of the sea decreases with the depth.

Supposing then that there were no other forces in action, the difference of level mentioned above, ought, as Maury at first admitted, to give rise to a surface-current from the equator to the poles, and an under-current from the poles to the equator. But these currents are enormously modified by the intervention of other forces. The north-east trade-winds react against this equatorial current of the northern hemisphere, exercising upon the surface of the sea an oblique pressure, of which the effect is greater than that of the difference of level. There results from this, reckoning from the 30° latitude, a rising of the

water in a direction contrary to the liquid masses which the south-east trade-winds tend to draw from the south Atlantic; at the same time the north-east trade-winds force the waters of the surface, as Franklin supposed, to take a south-western direction towards the Caribbean Sea. In this sea, and in the Gulf of Mexico, where the trade-winds exercise no influence, the water continues its course to the north by the Strait of Florida, and thus gives birth to the Gulf Stream. But in order to enable the Gulf Stream to advance from the Gulf of Mexico and the Strait of Florida as far as 30° N. latitude, a difference of level is necessitated, which can be calculated by the help of the general formulae for the movement of water in currents; by this means we find that the level of the water in the Gulf of Mexico ought to be about 6 feet higher than at St. Augustine. If we then observe that in accordance with the density of the water at St. Augustine, the level of the sea ought to be found to be about $3\frac{1}{2}$ feet above the point marked zero, which corresponds to the mean density of 1, it follows that the level of the Gulf of Mexico is about 9 $\frac{1}{2}$ feet above that point, and that the trade-winds are the means of adding a height of 3 feet to the water of that gulf.

After this immense current—which, in the Strait of Bimini, may be compared to a river delivering at the rate of 1,600,000,000 cubic feet per second—has passed St. Augustine, it pursues its course to the north-east, as has been said above. In order to accomplish this long passage, it has at its disposal, at the most, an incline of $3\frac{1}{2}$ feet; but it is easy to see that the force which results from this is altogether insufficient to accomplish the work which this movement demands, and it evidently follows that the Gulf Stream ought, during all this course, to be subjected to the action of another force, to which hitherto our attention has not been drawn. But what is this force of which we have thus taken no notice? Singularly, it is an old acquaintance, whose function we have not sufficiently understood, although Kepler was the first to announce its importance. In fact, the force which impels the Gulf Stream towards the north is simply that which results from the rotation of the Earth; and it acts not only upon the Gulf Stream, but, as we shall see, the chief cause of all currents, both atmospheric and marine. That the daily rotation of the earth should exercise an influence upon all currents which go from the equator to the poles and *vice versa*, and that the direction of the trade winds are due to the same cause, are facts well known. But though it is agreed that this rotation acts upon the currents of the ocean, opinion has hitherto been very much divided as to the importance of the action; some maintaining that the rotation of the earth is the chief cause why the Gulf Stream and the polar currents follow respectively the directions north-east and south-west, while others hold that it cannot cause any change to speak of in the courses taken by the ocean currents, courses which they would continue to follow all the same were there no rotation of the earth. But although there is so much dispute as to this point, every one agrees in acknowledging that we know but little about the matter, and in any case nothing certain of the laws which regulate the movements of the ocean and atmosphere; for we are at present ignorant whether the atoms of water or air move without resistance, or whether they meet and are subject to the action of certain forces, and we know still less about the origin of these forces, their magnitude, &c. This ignorance on the subject of the influence which the rotation of the earth exercises upon the currents is evidently due to the imperfect knowledge which we have of the laws which regulate the movement of fluids in currents; for if we had been able to establish that such a force ought to be in play, we would, without doubt, soon have determined the true expression. The thing is, in fact, very simple; if we suppose that a section of element current flows from the equator in the direction of the meridian in a definite channel, that line will turn with the earth with a

speed from west to east = $\frac{2\pi R}{86400} \cos \theta$, θ representing the latitude, and R the radius of the earth. After a time dt , during which the current in question will arise at latitude $\theta + d\theta$, it will act upon the sides of the canal as if it were subjected to a force which, in the time dt , had communicated to it

an increase of speed $\frac{2\pi R}{86400} \sin \theta d\theta$ from west to east, the line of current being supposed perfectly free. The force which results from the rotation of the earth could then be represented by

$$\psi = \frac{2\pi R}{86400} \sin \theta \left(\frac{d\theta}{dt} \right) = \frac{2\pi}{86400} \sin \theta v$$

v being the speed in the supposed channel. But the movement

not being free, since the material section which we are considering is forced to move in a channel from south to north, it will exercise per unit of mass against the sides of the canal, a pressure ψ directed from west to east. If the section, as we have supposed, forms part of a current compelled to move circularly in a channel, it is evident that the surface of the water will rise from left to right; and if we designate the height by what it rises by h , for a breadth of channel = l , we shall have — $g \frac{h}{l} = \frac{\sin \theta v}{13750}$.

The trajectory being the same, it is clear that the surface of the current ought to present the same slope, whether it moves in a channel or flows freely in the middle of the sea. But it is no less evident that whatever be the situation of this trajectory on the surface of the globe, the section which in the time t is found at latitude θ , and after the infinitely small time dt , arrives at latitude $\theta + d\theta$, ought, under the influence of the rotation of the earth, to move in the same manner as if, the earth being immovable, it had been driven from west to east with a force

$$\psi = \frac{2\pi R}{86400} \sin \theta \frac{d\theta}{dt} = \frac{\sin \theta v}{13750}$$

where v still represents the speed of the section under consideration, and θ the angle which the direction of the trajectory described makes with the eastern part of the circle of latitude. But we can, in consequence, put aside the rotation of the earth, and consider the latter as immovable if to the other forces which act upon the water, we add the force ψ acting from west to east. If we decompose this into two other rectangular forces, one of them following the direction of the current, which, let us suppose, has throughout its course a fall $\frac{du}{dL}$, we find that its surface

ought to present from left to right, and perpendicularly to the direction of the current, an elevation $\frac{h}{l}$, whose value is given by the equation

$$(1) \dots \dots \frac{h}{l} = \frac{\sin \theta \sin^2 \theta v}{13750}$$

and that the liquid mass is impelled forward by a force

$$\left[\frac{\sin \theta \sin \theta \cos \theta v}{13750} + \frac{du}{dL} g \right]$$

which, in accordance with my theory, leads to the following equation of the movement of the current:—

$$(2) u = \frac{V^2 - V_0^2 + 2V_0 V + V^2 + V_0^2}{2g} + \frac{H}{2g} + \frac{\sin \theta \sin \theta \cos \theta v}{13750} + \frac{V + V_0}{2g} L$$

where u is the fall of the current in the length L , H its depth, V_0 its initial speed, and V its final speed after having run the course L . In short, if, according to the theory, we place for the delivery of the current per second

$$(1) \dots \dots 2 = 0.82 V H L$$

we shall have the fundamental formulas which give the laws of the course of ocean currents over the whole surface of the globe; the angle θ , which is positive in the northern hemisphere and negative in the southern, having its values comprehended between 0° and 90° , while the angle θ_0 following the direction of movement, may be found in the 1st, 2nd, 3rd, or 4th quadrant.

It follows from these three formulas that all the currents of the northern hemisphere, whatever be their direction, have a surface which goes on rising from left to right, and whose progress, the force resulting from the rotation of the earth, accelerates or retards according as they move in the 1st or 3rd, or in the 2nd or 4th quadrant; hence it follows that a movement in one of these latter quadrants is possible only when the current possesses a sufficient fall, or an equivalent force, due, for example, to the action of the wind, the specific weight of the water of the sea, &c. When the current follows the meridian, the inclination of its surface, perpendicularly to its direction, is at the maximum; but besides this, the rotation exercises no influence upon its course. When the current flows at right angles to the meridian, the fall $\frac{h}{l} = 0$,

and the rotation has, in short, no effect upon its course.

If, then, we consider the Gulf Stream from its exit from the Gulf of Mexico, we see that, in its passage from Bimini to St. Augustine by the Strait of Florida, where it runs directly north, the current is kept up by a difference of level which, as has been stated above, may, for that extent, be estimated at six feet. Throughout this course the current presents from west to east an elevation whose total value is about 13 feet.

From St. Augustine to the Bay of New York the Gulf Stream

runs towards the north-east; in all this course it is impelled by the rotation of the earth with a force corresponding to a fall of from nine to ten feet, and rises from left to right about 1·2 feet.

From the Bay of New York the Gulf Stream runs eastward towards the shores of Europe, and, throughout the passage, obeys the impulse of the force of rotation, which raises it from left to right by a total elevation of about one foot. Having reached the neighbourhood of Europe, the current divides into two nearly equal branches, one of which, under the influence of the diminished force of the action of the earth's rotation, runs in a south-easterly direction towards the coast of Africa, with an elevation from left to right. The other branch, meanwhile, is forced to skirt the coasts of Great Britain, taking a more northerly direction on account of the resistance it meets with from the land, the action of the force of rotation causing it to advance in its northerly course with an elevation from left to right facing the land of one and-a-half feet. If we try to estimate the influence which the earth's rotation exercises upon the Gulf Stream from St. Augustine to the 60th degree of N. latitude, we find that the force is nearly the same as that which would act upon the current, if, between these two points, a distance of about 950 miles, the Atlantic showed a difference of level of twenty-five feet. When the Gulf Stream has passed the northern extremity of Scotland, the resistance which obliged it to take a more northerly direction disappears, and, from this time, the principal current inclines more to the east towards the coast of Norway, which it then skirts to the north-east, sloping towards the land on account of the earth's rotation. Another branch of the Gulf Stream is arrested by Iceland in its course to the north, and turned to the north-west, striving against the earth's rotation, which elevates it towards the south and south-west coast of the island just mentioned, it ought consequently to present a slope towards the north-west as far as the polar current.

(To be continued.)

SCIENCE IN GERMANY*

IN his address at the opening of the present University Session at Berlin, the out-going Rector quoted some interesting figures showing the effect of the recent war on the activity of the University. In October 1870 there matriculated in all the faculties 1,236 students, while the number of entries for the winter session of 1869 was 2,421. Of the 1,236 students who entered their names in October, only 904 continued their attendance throughout the winter. The actual number of medical students last winter was 173, while in the previous winter session they amounted to 550. The falling off in numbers extended about equally to all the four faculties; but it appears that none of the theological students who entered at the beginning of the session were required to break off their studies. The courses of lectures, public and private, that were announced amounted to 366, and of these 271 actually came off. Forty students took their degrees—8 in jurisprudence, 19 in medicine, and 13 in philosophy. The number of deaths, so far as was ascertained, amounted to 32. The University seems now to have returned to its full activity, to judge from the crowded state of many of the class-rooms. A few of the students are to be seen wearing the ribbon of the Iron Cross.

Two ladies from America have applied to the Berlin University authorities for permission to attend the medical classes. One lady, a Russian, is studying chemistry in Prof. Hofmann's laboratory. An American lady has been studying medicine at Breslau, and has sent to an American newspaper a glowing account of her friendly reception at the Silesian University. Another pioneer of the same sex is studying engineering at the Polytechnic School of Aix-la-Chapelle; and two ladies recently joined the University of Prague, where they are studying under the professor of history. During the past summer a solitary American lady, M.D., attended the Clinics at the Vienna General Hospital, and appeared to suffer, to the full extent, the inconveniences of being in so considerable a minority.

The autumn season on the Continent, as in England, is marked by the occurrence of various scientific gatherings. At several of these, Prof. Virchow has been receiving invitations, which the Berlin newspapers have chronicled from time to time. At the Assembly of German Naturalists and Physicians, held at Rostock, his speech was the great event of the meeting. During the Bologna Conference of Archaeologists, he was entertained at

a banquet by the Italian dignitaries and men of science; and at a scientific assembly held in Rome, the audience rose to their feet to welcome the celebrated Berlin professor, who made them a speech in French. In his address to the Rostock Conference, Virchow made some remarks upon the nature of annual scientific gatherings, of which he himself is an assiduous frequenter. "It was a matter of encouragement to me," he said, "when I read in the proceedings of the recent meeting of the British Association, in the opening address of its renowned President, Sir William Thomson, that Brewster, in his letter by which he called the Association into existence, expressly stated that he was led to this step from considering the great and beneficent results that the German Naturalists' Association (*Naturforscherversammlung*) had achieved during its nine years' previous activity. We were the first to advance among all nations; the English followed, and the number of these associations has gradually increased. They have, by degrees, extended into every possible province of human activity, and we have thereby become accustomed, by the co-operation of the many, to define more clearly the common objects at which the whole has to aim." And again, speaking of the results of these meetings, he says: "Not only the pleasures of fellowship, which are inseparable from a great congress of individuals; not only the amenities of personal acquaintance, which cannot be too highly valued; the forming of friendly ties, where, perhaps, under other circumstances, harsh and even bitter opposition would have sprung up; the reconciling of many controversial antagonisms through personal intercourse—all this is the smaller result. There is yet a greater—the communication of knowledge, the explanation of methods, the clearing up of the directions in which research should be undertaken—and these are things which can be no better told than by word of mouth." The main subject of Professor Virchow's address was the part that science would have to play in the new national life of Germany. Their work, he held, was to introduce into the popular life of the nation the great and all-pervading idea of evolution. Space will not permit even to give an abstract of his views.

Among the books that have issued from the German press within the last month or two are—the new edition of Virchow's "Cellular Pathology," much improved and enlarged; Professor Traube's "Contributions to Physiology and Pathology," in two bulky volumes, one containing experimental and the other clinical researches; a new instalment (the fifth) of Stricker's "Handbuch," a treatise on Leuchæmia, by Professor Mosler of Greifswald; and an elaborate work with plates, by Barkow of Breslau, on "Dilatations and Tortuosities of the Blood-vessels," with special reference to aneurism of the aorta in its various sites.

SCIENTIFIC SERIALS

THE fourth number of the *Zeitschrift für Ethnologie* for the present year begins with Dr. A. Erman's concluding part of his "Ethnological Observations on the coasts of Behring's Sea." He draws attention to the bold and often successful surgical treatment which was found to have been practised by the Aleutians when they were first visited by Europeans. The influence exerted by the Russians on these primitive people has tended to make them conceal, or even gradually relinquish the practice of many of their old national habits, and, amongst other usages, they have almost wholly given up their heroic surgical operations. Dr. Erman met, however, with one skilled Aleutian operator, from whom he learned many particulars in regard to the native practice of his art. It would appear that their variously-sized lancets are formed of finely-polished and sharply-edged flakes of obsidian. With these instruments bleeding in the leg as well as the arm is performed, and incisions made in various parts of the body, including the thoracic walls, for the purpose of removing blood or pus, in cases of their effusion into the cavity of the pleura, or in pulmonary disease. But although we are told that this practice is not found to be attended with any dangerous results, we are not informed how the injurious effect of any possible admission of air into the chest is guarded against. The Aleutians exhibit great dexterity in removing various parts of the bodies of whales, and of sea-lions and other seals which they have killed, as, for instance, the mucous membrane of the neck, without in any way injuring the contiguous parts. And they show wonderful skill in fabricating from such membranes thoroughly water-proof and highly elastic coverings for the feet and legs, as well as those invaluable rowing dresses known as "Kamlejes," which, when drawn over the head and upper part of the body and fastened

* From a Correspondent of the *British Medical Journal*.

down to the rowing seat, enable the Aleutian in his one-holed *baidarka* to bid defiance to the fiercest storm and roughest sea. Unlike their neighbours, the Kamtschadales, who, in their aversion to come in contact with a corpse, throw their dead to their dogs to be devoured and removed from sight, the Aleutians devote much time and care to the preservation of the body after death. This they do so effectually that they can keep the corpse in their dwellings for more than a fortnight without causing injury or annoyance to the living, while long after death the features and external appearance of the deceased remain unchanged. Dr. Erman supplies us with many valuable additions to our knowledge of the social habits, taste for ornamentation, traditional lore, language, &c., of the Aleutians. In counting the Aleutian employs 20 as his highest numeral, making all larger quantities dependent upon that number; thus, 40, 60, &c., are respectively 2, 3, &c., twenties. —In the second paper of the *Zeitschrift*, Dr. Robert Hartmann continues his careful summary of the remains of Swiss Lacustrine dwellings, passing in review the principal mammals represented in the deposits, and entering fully into the often-discussed question whether the diluvial Cave bear (*Ursus spelæus*), is identical in species with our common bear (*U. arctos*) or whether and to what extent it differs from it. Dr. Hartmann seems disposed in this inquiry to regard the question of identity as possessing strong claims to probability, although there may not be sufficient ground at present to answer it affirmatively. —“The Nirvana and Buddhistical Morality” forms the title of a very comprehensive paper by A. Bastian, which treats very fully of the principles on which the faith of Buddha is based, the ideas underlying the various forms which it has assumed, and the special phases of human thoughts and feelings to which it more particularly addresses itself. —In a paper by G. Rohlf, entitled “Henry Noël, of Bagerni,” the writer gives an account of the kingdom of Bagerni, which is situated on the N.E. of Lake Tsad, in Central Africa. The Bagerni people are a pure Ethiopian race, who, in point of moral and intellectual capacity, may be said to form the link between the most highly-developed negro kingdoms, and the numerous small negro states, lying to the S. of them, of which we do not even know the names. The King and Court of Bagerni, after a temporary adhesion to Islamism, have relapsed into their old Fetish worship, in which trees appear to form the principal objects of adoration. The practice of taking sisters and daughters in marriage prevails in the reigning family; but, while the rich indulge extensively in polygamy, poor men take only one wife. —Dr. Behnauer, of Dresden, gives a résumé of an official paper by the Assistant-Resident, Herr J. Riedel, of Batavia, on the geographical, topographical, and geological character of the districts of Holontalo, Limeto, Bone, Boalemo, and Kattinglo or Andigile in the Celebean Isthmus of the Eastern Archipelago. To this is appended much useful information in regard to the statistical, historical, and social condition of these countries, from which, however, we are not led to form a favourable opinion of the character, either of the Aborigines or of the Chinese and other foreign settlers. There are different grades of nobility, and till lately slavery and the slave-trade were allowed. Opium is undermining the health and vigour of the upper classes, and the poor are sunk in misery in the midst of an abundant vegetation, and with numerous sources of wealth around them; the mountains and river beds being rich in minerals. On the banks of the river Loncoo jumps of gold have from time to time been found as large as a hen’s egg. —The last paper in this number of the *Zeitschrift* that we can notice is one by Herr Neumayer on the intellectual and moral qualities of the native Australians.

THE *American Journal of Science and Arts* for October. The first paper in this number is “On the Connecticut River Valley Glacier, and other examples of Glacier Movement along the Valleys of New England,” by James D. Dana. In former papers by the author he has pointed out the existence of a Connecticut valley glacier in the glacial era, understanding by this expression that the under part of the great continental glacier, lying in the Connecticut valley, moved in the same direction. In the present paper the evidence with regard to this movement is gone into more fully, and further evidence is given to show that other large valleys of Central and Western New England had, in the same sense, their valley glaciers, that is the valleys determined the direction of the ice that lay within them. —Mr. R. Pampelly follows with a second contribution “On the Paragenesis and Derivation of Copper and its Associates on Lake Superior.” He gives a number of observations as to the minerals

occurring with copper in various mines. In many of the cases in which calcite crystals are found enclosing copper, it is difficult to distinguish as to the relative ages of the two. The author has, however, conclusive proof that each of the following cases occur:—(1) that the copper was present before the calcite began to form and became enclosed in the growing crystal; (2) the crystal of calcite was partly formed, then became incrustated with copper, and was finished by a new growth of calcite over the metallic film; and (3) the copper has entered the calcite crystal since its growth was finished. —A valuable paper follows, “On photographing Histological Preparations by Sunlight,” by J. J. Woodward. The arrangement which is found most suitable is to place the microscope at the window of the dark room, the body being horizontal, the achromatic condenser is then illuminated by a solar pencil, which is reflected from a heliostat on to a movable mirror. Between this mirror and the achromatic condenser there is placed a 2-inch lens of ten inches focal length, at such a distance that the solar rays are brought to a focus, and begin again to diverge before they reach the achromatic condenser. When a photograph is to be taken, a cell containing ammonium sulphate of copper is placed between the lens and condenser, working with a power of 500 diameters; the time of exposure was but a fraction of a second. By allowing the solar rays to come to a focus before reaching the achromatic condenser, the heat rays may be separated from the light rays by so adjusting the condenser as to bring the light rays to a focus, while the heat-rays, after passing the second lens, became parallel, or even divergent according to the position of the achromatic condenser. The author finds that a right-angled prism may be used instead of the heliostat, and in working with low powers a piece of plain unsilvered plate-glass is sufficient instead of the mirror. —The concluding original paper in this number is “On the Discovery of a New Planet,” by Dr. Peters, which will probably receive the number 116 of the asteroid group. The elements of the 114th asteroid have been computed, and are given, which show that this planet is not so small as was supposed. It is found to be now in the remotest part of its orbit, near its aphelion.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 16. —General Sir Edward Sabine, K.C.B., president, in the chair.

“Contributions to the History of the Opium Alkaloids,--Part III.” By C. R. A. Wright, D.Sc.

“On a Periodic Change of the Elements of the Force of Terrestrial Magnetism discovered by Prof. Hornstein.”

“Corrections and Additions to the Memoir on the Theory of Reciprocal Surfaces, Phil. Trans. vol. clx. (1869).” By Prof. Cayley, F.R.S.

“Corrections to the Computed Lengths of Waves of Light published in the Philosophical Transactions of the year 1868.” By George B. Airy, C.B., Astronomer Royal. The author, after adverting to the process by which in a former paper he had attempted the computation of the lengths of waves of light, for the entire series measured in the solar spectrum by Kirchhoff, from a limited number of measured wave-lengths, and to the discordances between the results of these computations and the actual measure of numerous wave-lengths to which he subsequently had access, calls attention to his remark that means existed for giving accuracy to the whole. The object of the present paper is so to use these means as to produce a table of corrections applicable through the entire range of Kirchhoff’s lines, and actually to apply the corrections to those computed wave-lengths which relate to spectral lines produced by the atmosphere and by many metals. Adopting as foundation the comparisons with Angström’s and Ditscheiner’s measures given in the former paper, and laying these down graphically, the author remarks that in some parts of the spectrum the agreement of the two experimenters is very close, that in some parts they are irreconcilable, and that in one part (where they agree) there is a peculiarity which leads to the supposition that some important change was made in Kirchhoff’s adjustments. He then explains the considerations on which he has drawn a correction-curve, whose ordinates are to give the corrections applicable to his former computed numbers. A

general table of corrections is then given, and this is followed by tables of the lengths of the light-waves for the air and metals as corrected by the quantities deduced from that general table. The author remarks that he has not yet succeeded in discovering any relation among the wave-lengths for the various lines given by any one metal, &c., which can suggest any mechanical explanation of their origin.

Zoological Society, November 21.—Prof. Flower, F.R.S., V.P., in the chair. Mr. Slater exhibited and made remarks on a fine skin of *Atles variegatus* Wagner (*A. bartolletti* Gray) which had been received in a collection from Oyapok, on the eastern limits of Cayenne, being a new locality for this species.—A communication was read from Prof. Owen, F.R.S., containing the third of a series of memoirs on the osteology of the Marsupials. In this memoir Prof. Owen entered at full length into the modifications observable in the cranium of the three known species of Wombats (*Phascolomys*).—Dr. Günther, F.R.S., read a report on several important collection of Fishes which had been recently obtained for the British Museum collection. Amongst them were many new forms from the Pacific, obtained through the agency of the Museum Godeffoianum of Hanburgh; several novelties from Celebes, collected by Dr. B. Meyer; and some interesting fishes from Tasmania, transmitted by Mr. Morton Allport. Dr. Günther called special attention to the occurrence of many well-known European forms of fishes in the Australian seas, and in explanation of this fact, suggested that these might also occur as deep-sea fishes in the intermediate seas of the tropics.—A paper by Mr. A. Anderson was read, containing notes on the Raptorial Birds of North Western India.—A communication was read from Messrs. G. Stewardson Brady and David Robertson, giving descriptions of two new species of British *Holothuridae*.—Mr. P. L. Slater exhibited and described, under the name *Turtur albebrunus*, a specimen of a new species of Dove of the genus *Turtur*, from the coral reef of Aldabra, north of Madagascar. This specimen had been lately living in the Society's Gardens, having been presented by Mr. E. Newton.—A paper by Mr. John Brazier, of Sydney, N.S.W., was read, giving descriptions of seven new species of the genus *Helix*, and of two Fluvialite Mollusks from Tasmania. A second paper, by Mr. Brazier, containing notes on the specific names of certain Land Shells from the South Sea Islands.—A communication was read from Count Thomas Salvadori, containing a note on *Cerionis caboti*.—A communication was read from Mr. W. T. Blanford giving a description of a new Himalayan Finch, proposed to be called *Procarduelis pubescens*, from Sikim.

Anthropological Institute, November 20.—Sir John Lubbock, Bart., M.P., president, in the chair.—Captain R. T. Burton, late H.M.'s Consul, Damascus, read a paper on "Anthropological Collections from the Holy Land." Captain Burton having unexpectedly returned to England, under the peculiar circumstances now publicly known, travelled to Palmyra from Damascus between April 5 and April 20, 1870, and has brought home specimens of the Palmyrene mummies, the first which have seen the light in England, statuettes, beads, coins, and other articles calculated to throw light upon a subject hitherto left in the gloom of antiquity. On some of the figures described were emblems illustrative of the Phallic and other mysteries, and according with similar reliques found at Nineveh.—Dr. Carter Blake read a long note on the human remains discovered by Captain Burton at Palmyra. These indicated an entirely different race from that which inhabited modern Syria, and the skulls afforded many points of resemblance to the ancient Phœnicians which have been described by other anthropologists. The men were of large stature, in one case reaching probably about 6 feet 4 inches. There were among these remains not one which could be confidently referred to the Hebrew race, a fact on which the author laid stress, without offering any comment. Minute descriptions and measurements of all the specimens were given. Captain Burton will read further papers before the Anthropological Institute, and describe, with topographical notes, the various objects of silex and others which he collected during his 22 months of service in Syria and Palestine.

Entomological Society, November 20.—Mr. A. R. Wallace, president, in the chair. The following gentlemen were elected: Mr. C. V. Riley, State Entomologist for Missouri, as foreign member; Lieutenant B. Lowley, R.E., and Mr. F. Raine, as ordinary members; and Mr. W. H. Milkin as a subscriber.—With reference to Prof. Westwood's exhibition of *Formica herculeana* (at the last meeting), found in the crop of a great black woodpecker said to have been shot near Oxford, Mr. Dunning

remarked that, according to information received, several examples of this bird (presumably of foreign origin) were exposed for sale in the London markets at the precise time of its supposed occurrence near Oxford. Prof. Westwood had information from Messrs. Robertson and Jackson that it occurred in Devon; the former gentleman affirming that he had repeatedly seen it at Clovelly. Mr. F. Smith was informed that thirty examples had been recorded as British, and that one in particular had been shot by the grandfather of the present Lord Derby. Mr. Jenner Weir reiterated his belief in the species not being British, and Mr. Bond said that every recorded instance had been traced and found to be erroneous, save Lord Derby's example, concerning which doubt existed. Mr. E. Sheppard could not reconcile the occurrence of a gigantic ant, not hitherto known as British, in the crop of a bird, the origin of which was open to doubt, with the idea of the former being an addition to the British Fauna. Mr. McLachlan suggested that Prof. Westwood should visit the locality in which the bird was said to have been shot, and search for the ant. The discussion ended by Prof. Westwood promising to furnish further evidence.—Mr. Bond exhibited small pale examples of *Lasiocampa trifolii*, which appeared to form a distinct race; also females of *Climacampa castralis*, with the wings on one side assuming male characters, without any evidence of gynandromorphism.—Mr. Stinton exhibited a variety of *Agrotis comes* (*Triphena orbata* of collection), captured near Exeter by Mr. Dorville.—Mr. Smith exhibited the cocoons of the American *Tiphia larda*; these were double, consisting of a flimsy outer casing, and a hard inner cocoon. He expressed his belief that the larvae of the *Tiphia* devoured those of *Aphodius*. Mr. McLachlan brought before the notice of the meeting an instance of mimetic resemblance between two common North American *Libellulidae*. The insects in question were *Libellula pulchella* Drury, and *Plathemis trimaculata* De Geer. In the former the sexes were nearly similar in appearance; in the latter very dissimilar, and the female almost precisely resembled that of *Libellula pulchella*. During the discussion which followed, the question was raised as to the liability or non-liability of dragon-flies to the attacks of birds. Mr. F. Smith had seen swallows devouring *Agrotis*, and Mr. Briggs had observed a contest between a sparrow and a large dragon-fly in the streets of London, in which the former was obliged to retreat. It was recommended that American entomologists should observe the habits of these two species, and suggest a reason for the close mimicry existing between them.—Mr. Müller related that he had found the larvae of a *Thrips* to be destructive to peas, by eating the outside of the green pods.—Mr. McLachlan read notes on the confusion existing in the nomenclature of the common European *Myndodesmidae*, in consequence of Linnaeus having confounded them in his descriptions.—The publication of a further portion of the proposed general Catalogue of British Insects (*Hymenoptera Aculeata*, by Mr. F. Smith) was announced.

Linnean Society, November 16.—Mr. G. Bentham, president, in the chair.—"On the Floral Structure of *Impatiens fulva*," by A. W. Bennett, F.L.S. The author described the closed "cleistogamous" flowers of this plant, which are far more numerous than the well-known conspicuous flowers, and which produce nearly all the seed-vessels, being abundantly self-fertilised. He suggested that the "cap" formed by the calyx and corolla in these closed flowers is thrown off by the elasticity of the stamens, which are entirely different in structure from those in the conspicuous flowers, the anthers never dehiscent, but the pollen putting out its pollen-tubes while still in the anther, and piercing the wall in order to come into contact with the stigma. In the conspicuous flowers there is a peculiar arrangement in the form of a membrane attached to the stamen-tube, which prevents the access of pollen to the stigma, and as they do not appear to be visited by insects they seldom produce seed-vessels.—"Flora Hongkongensis Supplementum," by H. F. Hance, Ph.D. In this paper a large number of new species are described, increasing the number included in Bentham's "Flora Hongkongensis" by about one-seventh.

GLASGOW

Geological Society, November 2.—Mr. John Young, vice-president, in the chair. Mr. James Thomson, F.G.S., laid before the meeting some portions of curiously-spotted clay which he had obtained during the recent excavations to the east of the old College of Glasgow. He stated that the occurrence of white spherical spots in the Old Red sandstone, particularly in the neighbourhood of Dumbarton, had often been remarked by the members, and various opinions had been expressed as to the pro-

bable cause of the discolouration. Having observed similar spherical markings in a bed of dull red clay which was being excavated near the old College, he secured several portions of it, which, after drying, split freely and exposed both discoloured spots and lenticular patches similar to those found in the Old Red sandstone referred to. On examination, he observed in the centre of each discoloured spot faint indications of some foreign body, which, on closer scrutiny, proved to be decayed vegetable matter; and on further breaking up the clay, he found the matrix around this vegetable matter always more or less discoloured, while the fibrous or woody matter itself was nearly black. He suggested that the phenomenon was due to the chemical affinity of the oxide of iron in the clay for the constituents of the vegetable matter, and that the discoloured spots in the red sandstone might be due to a similar cause, though no trace remained of the organism by which they were occasioned.

DUBLIN

Royal Geological Society, November 8.—Edward Hull, M.A., F.R.S., Director of the Geological Survey of Ireland, in the chair. G. H. Kinahan, M.R.I.A., read a paper on the Coal Measures of Ireland. This paper was in reply to some statements made by Mr. Hull at a former meeting of the Society in regard to the work of the late Mr. J. B. Jukes and his colleagues. Mr. Hull had stated that, while true Coal Measures existed in Connaught, there were none in either Leinster or Munster. The author argued that this assertion was quite erroneous, and that the Coal Measures of these three provinces were identical. Mr. Hull, in reply, seemed to argue that the lower Measures in Munster and Leinster were very similar to the so-called Yoredale rock and millstone grits of England, but acknowledged the general correctness of the maps published under Mr. Jukes' direction. Rev. Dr. Haughton moved that Mr. Kinahan's paper be published, and expressed his belief that all such subjects were much better discussed on published data.—Rev. Dr. Haughton F.R.S., read a note from Mr. Richardson, secretary to G. R. Graves, M.P., of Liverpool, informing him that the *Neptune*, Captain Edwards, had just put in from Quebec, and that the Captain reported that on the 12th October, at sea, in lat. 46° N., long. 35° W., at about 4 P.M., blowing strong from W., he observed a dense cloud of fog arise on the western horizon, which gradually came up with and surrounded the vessel, and so continued until midnight. From first coming up with the ship until clearing off, there prevailed a very strong smell of burning wood, both the Captain and crew felt their eyes much irritated by the smoke, and the decks were strewn with fine dust. At the time the ship was more than 2,000 miles from Chicago.—Prof. Macalister exhibited for the President, Lord Enniskillen, the skull of *Ursus ferox* found in the County of Monaghan.

Royal Irish Academy, November 13.—The President, Rev. Dr. Jellott, in the chair.—Dr. Whitley Stokes read a paper "On the Féilire of Oengus." This ancient Irish MS., of which Dr. Stokes presented a translation to the Academy, although it, he said, was of but little literary merit, possessed from the purity of its vocabulary considerable value to the student of comparative philology, revealing very fully the position which the Celtic occupied in the great Aryan family of languages. Dr. Stokes illustrated his views by the comparison of many words with their cognate forms in Greek, Latin, Sanscrit, &c. He also explained the structure of the metre in the poem, and mentioned the several copies of the MS. in existence.—Prof. R. Ball read a paper, written by his brother, Valentine Ball, B.A., of the Geological Survey of India, "On the Andaman Islands," in which he gave a short account of a visit to the "Home" at Mount Augusta, which he made in company with Mr. Humphrey, who is the superintendent of the Home, and Dr. Curran.—Prof. Ball read a paper "On a Geometrical Study of the Kinematics, Equilibrium, and small Oscillations of a Rigid Body."—G. H. Kinahan read a paper "On the Granitic and other Ingenite Rocks of the Mountainous track of Country west of Loughs Mask and Corrib." The term Ingenite he adopted from David Forbes.—

PARIS

Academy of Sciences, November 13.—M. Dumas noticed the loss which the Academy had sustained in the death of its foreign associate, Sir Rodenick Murchison, of whom he spoke in high terms.—M. F. du Moncel read a note on the most economical arrangement of voltaic piles with respect to their polar electrodes, in continuation of a former note.—M. Faye presented a note on the spectroscopic measurement of the rotation of the sun by means of Dr. Zollner's reversion spectroscope, in which he stated

that Dr. Vogel of Bothkamp, near Kiel, had succeeded in effecting this measurement, and ascertained a velocity of rotation of 2,497 metres per second.—M. Faye also communicated a memoir on the law of rotation of the sun, in reply to a reclamation by Father Secchi, and a memoir by Dr. Zöllner; in this he indicated the reasons which led him to the belief that the sun is a gaseous body.—M. Le Verrier announced that but few meteors had been observed in France on the night of the 12–13th November.—M. Phillips read a paper on the governing spiral of chronometers.—M. H. Resal presented a note on the movement of a material system referred to three rectangular axes capable of moving around their origin.—General Morin communicated a memoir by M. Tresca on the results of experiments of flexion made upon steel and iron rails beyond the limit of elasticity.—A note by M. W. de Fonville was read relating to an observation made by M. Jansen on the stoppage of the rotation of the car of a balloon.—MM. Becquerel presented a memoir on the temperature of soils covered with low vegetation or denuded. The observations were made at various depths below the surface, from five to sixty centimetres, and showed that the mean temperature during the months of August, September, and October is lower under a denuded surface than under one covered with herbage.—M. C. Sainte-Claire Deville noticed the observation of faint aurora borealis in France on the evening of the 9th November.—A memoir, entitled "Thermic Investigation on Crystalline Dissociation," by MM. P. A. Favre and C. A. Valson, was read. The authors remarked upon the variety of phenomena involved in the solution of a crystalline salt in water, which they proposed to study from the thermo-chemical point of view, and tabulated and discussed the results of the solution of a long series of crystalline salts, chiefly sulphates.—M. E. P. Bérard presented a note on the *salant*, or saline crust, which is formed on the shores of the Mediterranean upon certain unproductive soils. Common salt is the chief ingredient in this crust.—M. Berthelot communicated a continuation of his memoir on the formation of precipitates, in which he discussed the thermal phenomena associated with the separation of the acid of salts from the base.—M. Maumené presented a note calling attention to the fact that he had some years ago indicated the possibility of the slow transformation of cane sugar into glucose.—M. J. Decaisne communicated some observations on the Pomaceae, the chief object of which was to indicate the characters by which this important group of plants may be divided into good natural genera.—M. Bossin and M. Baudet communicated suggestions for the destruction of *Phylloxera vastatrix*.—M. Claude Bernard presented a note by M. Ranvier, on the Histology and Physiology of the Peripheral Nerves.—M. Milne-Edwards presented a note on *Oncidium ciliatum*, by M. L. Vallant, in which the author described the anatomy of that curious gasteropod, and expressed the opinion that although rightly placed among the Pulmonata, it presents certain affinities with the Opisthobranchiate mollusca.—M. de Quatrefages communicated a note by M. E. Perrier on *Eudrilus*, a new genus of Lumbricina from the West Indies.—M. Méné presented some investigations on the fat of domestic animals.

November 20.—A paper was read by M. de Saint-Venant on the mechanics of ductile bodies.—M. H. Resal presented a memoir on the movement of a point subjected to the action of a periodical cause, which experiences a constant resistance directed in the inverse direction of the velocity; M. C. Rozé a note on the asymmetry of the terminal curves of the spiral spring of chronometers; and M. de Saint-Venant a memoir by M. J. Boussinesq on the theory of the undulations and movements which are propagated along a rectangular horizontal canal when there is communicated to the liquid contained in this canal like velocities from the surface to the bottom.—M. Yvon Villarceau communicated extracts from a letter from Mr. Gould relating to the establishment of an Observatory at Cordoba in the Argentine Republic.—M. Le Verrier communicated a note giving the results of observations of meteors made in France on the 12th, 13th, and 14th November. Those observed on the 12th and 13th issued from a point in the neighbourhood of the constellation Auriga; the "Leonides" or meteors issuing from Leo were most numerous on the night of the 14th. M. Faye made some remarks on this communication, and to these M. Le Verrier replied.—M. Chapelas also presented a note on the meteors of November 1871.—M. Le Verrier presented a note by M. de Gasparis on the formulæ for calculating the orbits of double stars.—M. P. A. Favre read a continuation of his thermic investigations upon electrolysis, in which he discussed the thermic phenomena observed during the electrolysis of sulphate of copper, sulphate of zinc, nitrate of copper,

and mixtures of neutral sulphates of zinc and copper with sulphate of hydrogen.—M. Elie de Beaumont made some remarks upon the Mont Cenis tunnel, and read a letter from Father Secchi on the pendulum experiments which it is proposed to make in the tunnel.—M. J. Bourget presented a paper on the velocity of sound in sonorous tubes.—M. Jamin communicated a note by M. E. Gripon on the transverse vibrations of wires and thin plates, and also a note by M. Alvergniat on a new phenomenon of phosphorescence produced by frictional electricity. According to the latter a small quantity of chloride or bromide of silicon hermetically sealed in a vacuum tube gives a bright luminosity when the tube is rubbed with a piece of silk. The chloride gives a rose colour, the bromide a greenish yellow.—M. Le Verrier presented a note on the history of the observations on the action of eclipsic conjunctions upon the elements of terrestrial magnetism, by M. Moise Lion.—M. Le Verrier also presented a note by M. Tarry, giving an account of an aurora borealis observed at Brest on the 9th November, in which the author noticed particularly the perturbations manifested by the apparatus employed in telegraphy.—M. Le Verrier also remarked that auroras had been observed in Piedmont on the nights of the 2nd, 9th, 10th, and 15th November, and referred to the coincidence between the occurrence of these phenomena and the November flight of meteors, which M. C. Sainte-Claire Deville supposed to exist.—M. Berthelot read the conclusion of his paper on the formation of precipitates. In this he discussed the changes which take place in the state of aggregation of precipitates, illustrating his views by the facts observed in the cases of the carbonates of strontia, baryta, lead, and silver, and of the oxalates.—M. Wurtz presented a note by M. E. Ritter on the transformation of albuminoid matters into urea by permanganate of potash. This note contained an experimental confirmation of M. Béchamp's statement.—M. de Quatrefages communicated an extract from a letter by M. E. S. Delidon, on the butts of Saint-Michel-en-l'Herm, and on the means by which their elevation above the sea, and other local elevations, may have been effected. He considers that local elevations may be due to infiltration of fresh and salt water.—Mr. E. Blanchard presented a note by M. S. Jourdain on the anatomy of the sunfish (*Orthogoriscus mola*).—An extract of a letter from M. A. Poey to M. Elie de Beaumont, on the influence of violet light upon the growth of the vine, pigs, and cattle, was read.—M. de Quatrefages presented a note by M. F. Garrigou on lacustrine habitations in the Pyrenean region of the South of France. In this note the author describes the results obtained by him in the investigation of the deposits of ancient lakes at the foot of the Pyrenees.

BOOKS RECEIVED

ENGLISH.—Becton's Medical Dictionary (Ward, Lock, and Tyler).

FORAIGN.—Anales del Museo publico de Buenos Aires; Entrega octava: por German Burmeister (Paris, Savvy). (Through Williams and Norgate).—Beiträge zur Parthenogenesis der Arthropoden: von Siebold.—Lehrbuch der chemischen u. physikalischen Geologie: G. Bischof.—Untersuchung des Weges eines Lichtstrahls durch eine beliebige Anzahl von brechenden sphaerischen Oberflächen: P. A. Hansen.—Die Arachniden Australiens nach der Natur beschrieben und abgebildet: Dr. L. Koch.

PAMPHLETS RECEIVED

ENGLISH.—On the Formation of the Cirques of Brittany: Rev. T. G. Bonney.—Law of Husband and Wife: Philo-milias.—The Objectives to Science Teaching in Schools: Rev. W. Luckwell.—Educational Hospital Reform: T. J. Boyd.—Report of Science and Art Department of the Committee of Council on Education, South Kensington.—Directory, with Regulations for Establishing and Conducting Science Schools.—Flints, Fancies, and Facts: a Review: W. Robinson.—Cases of Diarrhoea: Dr. Chapman.—Apprenticeship to the Sea Service: a Circular of the Board of Trade.—Proceedings of the Bristol Naturalists' Society, Vol. iv., part 1.—Glaciation of the North-west of England: C. E. de Ranke.—Cholera and Disinfection; Asiatic Cholera in Bristol in 1865: Dr. Budd.—Primary Schools and the Difficulty of Spelling: E. Jones.—On the Effect of Small Variations of Temperature on Steel Magnets: Gordon and Newall.—Prize Medals of the Royal Geographical Society.—General Representation on a Complete Readjustment and Modification of Mr. Hare's Scheme: A. E. Dobbs.—Reply to John Hampden's Charges against Mr. Wallace.—The Variations at Different Seasons of a *Hieracium*: Prof. Balfour.—Quarterly Journal of Education, October.—Fifteenth Annual Report of the Medical Officer of Health of St. James's.—On the Pre-glacial Geography of Northern Cheshire: C. E. de Ranke.—Man contemplated Physically, Morally, Intellectually, and Spiritually: J. W. Jackson.—Introductory Lecture on Experimental Physics: J. Clerk Maxwell.—On Ocean Currents: J. K. Laughton.

THE CHAIRS OF SCIENCE IN THE
SCOTTISH UNIVERSITIES

THE biographer of a Scottish Professor says (we fear boastfully) that his friend had lectured on anatomy, chemistry, physiology, pathology, medical jurisprudence, and medicine, and that he was well qualified also to lecture on botany, mineralogy, and geology. There were giants then surely, but their day is past; for the Professor of Natural History in Glasgow University is just now trying to procure the erection of a new Chair, on the ground that geology or comparative anatomy is, either of them, as much as he can effectively teach. Perhaps no better indication of the enormous progress of Science during the last half century could be found than the facts we have mentioned. The earlier professor found his multifarious duties possible because the subjects were very limited, and, in physiology, chemistry, mineralogy, and geology, the means of investigation were few. Now geology has outgrown the dimensions of anatomy, as a teaching subject. The Chairs of Natural History in Scotland, now only two in number, those in Glasgow and Aberdeen (for Science is only provided for temporarily in St. Andrews at present at the cost of Civil History), are remarkable foundations. There is no clear notion what the Professors may not teach. Custom has settled that geology and zoology shall be expected of them, and the Ordinances of the University Commissioners act upon this tradition. But it is doubtful if successful restraint could be put upon an eccentric Professor who selected ethnology and meteorology as his topics. He would lose class fees; but as he holds from the Crown, and the Crown has not defined his duties, he would be legally safe. Fortunately there has been no attempt hitherto to act independently of University needs; on the contrary, there have been from time to time voluntary modifications of the class work, both as regards the length of the courses and the subjects, so as to meet the needs of students. But this very complaisance has been injurious; for, to take the case of Glasgow, the Universities (Scotland) Act made zoology a compulsory subject for medical students, and the Court and Senate at a later date resolved to grant a degree in Engineering Science (modestly calling it a certificate), requiring geology as one of the subjects of examination. Complete systematic courses were therefore indispensable, and the attempt to provide these has demonstrated their impossibility; hence the present attempt to procure a change.

While sympathising with the Glasgow Professor, and with his colleagues in Aberdeen and in Queen's College, Ireland, we decline to discuss the question as one of individual hardship, or even as detracting from the efficiency of one or several Universities. The existence of lectureships which profess to be scientific, but which can only be popular if the work is equally divided between the different subjects, is an evil which demands a remedy, and Scotland cannot be indulged in her fancy for multiple Chairs, as anatomy and botany, logic and rhetoric, moral philosophy and political economy, civil and Scots law. If the teacher has a strong

bias in favour of either subject he will throw himself into that and neglect the other, even though it forms part of that curriculum for which a degree is granted. Now, apart from the degradation of a scientific honour, the lowering of the standard of scientific teaching is especially to be guarded against at the present time. There are too few inducements for young men to devote themselves to Science as a life profession, still less encouragement do they receive to devote their energies to one branch exclusively. If our Universities continue to sanction average teaching, it will be a substantial injury to education throughout the country, and will put an end to that scientific work upon which the progress of science and the reputation of the country ought to rest: for it cannot be expected that a man whose ideas are frittered away by desultory work can have either the inclination or the time for patient continuous research. It is to be regretted that the Scottish Universities are too poor to help themselves in this matter. Private liberality has placed Edinburgh in a right position; geology and zoology being respectively the entire occupation of Geikie and Wyville Thomson. In Newcastle the new college has started wisely with one subject, geology; but it is to be hoped that zoology will ere long be added as a separate professorship. In the London colleges separate provision, such as it is, is made for these two branches of Science, and even in the Universities which flippant so-called Radicals are wont to denounce as effete, and to contrast unfavourably with their Scottish sisters, there is provision for teaching as well as for the teacher.

It is in the interest of these and other bodies that we urge the necessity of reforming Scottish Universities in the matter of Science teaching. If they are permitted to continue as at present, the good done by their better equipped rivals will be diminished. It is a mistake to suppose that one college is better off if the teaching in another is defective; that may happen for a year or two, but in the end all suffer for the fault of one, all are lowered in tone though they may not be brought equally low. To maintain English teaching, Scottish teaching must be raised. But as no funds exist on which a just claim may be established for this purpose, private generosity or the State purse are the only appeals. Cabinet Ministers have been known to talk of Science as having condemned itself if it is not self-supporting, and in London there is a current opinion that Science is too largely subsidised, comparatively speaking, north of the Tweed. But it must be remembered that in Glasgow and Aberdeen, even in Edinburgh, it is impossible, save in the exceptional case of the director of the Scottish Survey, to find a man qualified for the post, and at the same time deriving an adequate income from other sources; for the time is past when Science was the pursuit only of the wealthy. It may not be sound in principle, but it is a practical necessity for the State to endow Science in the provinces; failing that and failing local effort, it would be best, in the interests of sound education, to suppress the starved chair altogether. But in the particular cases at present under consideration there is a strong claim on the State; the chairs of Natural History are creations of the Crown, and as circumstances have altered greatly since their creation, it behoves the Crown to secure that its intentions are fulfilled by making corresponding alterations.

Of course this is the final resort after it is clear that Scotsmen decline to supply the money needed; but in Glasgow at least it is not to be believed that the examples of Manchester, Birmingham, and Durham will be without effect. All that has been said is equally true of Ireland; but the practical treatment of the difficulty involves other considerations upon which we cannot at present enter.

JUKES'S LETTERS

Letters and Extracts from the Addresses and Occasional Writings of J. Beete Jukes, M.A., F.R.S., F.G.S.
 Edited, with connecting Memorial Notes, by his Sister, with a Portrait. (London: Chapman and Hall, 1871.)

HOW few among us—when his glass is run—would care to have the story of his life from year to year, even from his boyish days, writ down and published to the world—indeed, how very few would be found worthy of more record than “born, lived, died.” Now and again, however, one meets with a man whose career in life is not only lifted above the monotonous hum-drum existence of ordinary mortals, but who, both by his life and writings, attracts our admiration and regard.

Such a man was Joseph Beete Jukes, a sketch of whose life and writings, together with some two hundred letters, edited by his sister, Mrs. A. H. Browne, form the substance of this volume.

Blest not only with a goodly person and stature but with a noble and generous nature, which won to his side both the ignorant and the educated, Mr. Jukes was also a man of high mental endowments, and both as a speaker and a writer had the knack to command attention. But in his leisure hours no one entered more keenly than he into all the enjoyments of the country, being fond of hard riding, and a keen sportsman and good shot. Nor was he less fond of a good joke, as his letters often testify.

Educated at Cambridge during Sedgwick's palmy days,* no wonder that he caught some of the fire from “Old Adam,” as his students lovingly nicknamed him, and instead of entering the Church, as his mother fondly hoped, inaugurated a career for himself by walking through Derbyshire, Staffordshire, Cheshire, Shropshire, Yorkshire, and many other parts of England, geologising and lecturing wherever he could get a class to attend. And very successful Jukes seems to have been. Writing from Nottingham in June 1838, he says, “I have had a very good class here, never less than two or three hundred, and frequently four or five hundred” (p. 26).

Having about 1838 made himself acquainted with practical surveying, he was in 1839 offered the appointment of Geological Surveyor of Newfoundland, a post he gladly accepted, and which occupied his time until the close of 1840. Into all the hardships of this work he entered with his accustomed good-will and spirits. Mr. Jukes contrasts his own easier lot with that of the hardy naturalist Prof. Stüwiz, who “set off at the beginning of December in a boat with a little cuddy, to which (he says) my cabin is a palace, to see the winter fishing in Fortune Bay, with the chance of being frozen up on his return, and having to get ashore and come through the woods and snow,” and he adds, “don't talk of my hardships and privations and courage” (p. 91). But the Newfoundland survey ended

in October 1840,* and early in 1842 Mr. Jukes had the satisfaction to find himself appointed to the office of Naturalist to the Expedition for surveying Torres Straits, New Guinea, &c., on board H.M. ship *Fly*, commanded by Captain E. P. Blackwood, R.N. This task, so congenial to him who loved no occupation so well as one requiring constant out-door exercise in the saddle, on foot, or on the water, occupied him until June, 1846, and during his four years' absence his letters and journals furnish abundant materials of interest to the reader; much of which, however, will necessarily also be found in Mr. Jukes's book entitled “Narrative of the Surveying Voyage of H.M.S. *Fly* (2 vols.), published in 1847.

His description of scenery in the interior of Java is very interesting:—“Rich plains covered with all kinds of tropical productions, watered in every direction by clear rocky brooks, surrounded by mountains, either in single cones or serrated ranges, from 5,000 to 11,000 feet in height; abundance of game whenever we choose to stop and shoot, jungle-fowl, peacocks, deer, wild pigs, tigers. We crossed one great range of mountains by a path that led us through the extinct crater of a volcano, five miles across and 7,000 feet above the sea, and in the centre of which was a small cone and crater still in action, though when we looked down into it it was only blowing out steam, with a roar as of a thousand blast-furnaces. Take a scene on the slope of these mountains, as they dip into the plain of Malang. Scene:—An open mountain valley, full of coffee plantations, with small scattered villages, into which opens a deep mountain glen, crowded with the rankest luxuriance of tropical vegetation, groups of tree ferns and great broad-leaved plants, so as to arch over and frequently hide altogether the full brook that comes flashing and roaring down the rocks in a succession of rapids, varied by waterfalls; the road, narrow, steep, and slippery, as it winds down the sides of the glen, expands into a broad green lane, with an exquisite carpet of turf as it opens on the more level lands” (pp. 238, 239).

Like every other man who is fond of the sea, we find him exclaiming, “I confess I am getting more and more enamoured of a sailor's life, and regret I did not know the navy early enough to enter it. I see it would have suited me exactly” (p. 251).

But Mr. Jukes was destined to be a geologist. On the return of the good ship *Fly*, in June 1846, he only allowed himself a few weeks at home before he had again “signed articles” to Sir H. T. de la Beche, then Director-General of the Geological Survey, and in October joined Profs. Ramsay and Forbes at Bala. These appear to have been his most intimate friends, as his letters to Ramsay abundantly attest. His letters to Forbes have, unfortunately, not been preserved. To those not connected with the Survey, this is the section of the book which it seems to us will be the least interesting, although here and there one comes upon a funny bit or a matter of public interest.

His fagging away at the geology of the rocks south of Conway forms the subject of many letters, and the solution of their puzzling structure is well given at p. 306. For

* For an account of his Newfoundland experiences and travels, see also “Excursions in and about Newfoundland during the years 1839 and 1840,” 2 vols. 8vo, London, 1842. See also “Report on the Geology of Newfoundland,” folio, 1840.

* He matriculated at St. John's in 1830, being then nineteen years of age.

comical bits, the story of a new fossil discovered (p. 314); the boundary of the Caradoc Sandstone at Pentre Voelas (p. 318); and "a strange and marvellous history of a temptation and what befel thereon" (p. 323), must be read and laughed over, as also must the account of Miss Moggore and Miss Bood, natives of Murray and Darnley Islands, who *would* walk arm-in-arm with Mr. Jukes (p. 252).

Besides a vast number of letters to Prof. Ramsay, all more or less relating to geology, there are letters to Dr. Ingleby and other relatives; one on Versification (p. 377), in which two of Mr. Jukes's own verses appear. The annexed is a sample, probably intended for the Old Annual Survey Dinner:—

Free o'er the hills our feet shall roam,
We'll breathe the mountain air, sir;
Care shall not ever dare to come,
Nor grief pursue us there, sir.
Joyous in Nature's wildest scene,
Where rocks lie topsy-turvy,
And falling waters flash between,
We'll prosecute the Survey.
Oh, the Survey, the Geological Survey!
Health and good humour shall be queen
Of the Geological Survey!

We have religious beliefs considered (p. 375); views on Providence (p. 386); creeds (p. 409); political opinions (p. 405), and many other matters discussed.

But we have said sufficient to recommend the book to all who are likely to be interested in it. We would especially direct geologists to it, as being the record of the life of a man who did very much for their science—indeed, who died in its service. To his friends, who are to be found scattered far and wide, the title of the book is sufficient to recommend it to them. To his relatives and intimate companions his memory will always be dear.

It seems strange that Prof. Jukes's life should be dedicated to Prof. Sedgwick, his early teacher; but so it is—the old oak, though decayed and feeble, still puts out its green leaves; but the younger man, whom he bid God speed thirty years ago, has already rested from his labours.

H. W.

OUR BOOK SHELF

The Science of Arithmetic. By James Cornwell, Ph.D., and Joshua G. Fitch, M.A. Thirteenth Edition. (Simpkin, Marshall, and Co., 1870.)

The School Arithmetic. By the same authors. Eleventh Edition. (Simpkin, Marshall, and Co., 1871.)

THESE books are too well known to mathematical teachers to need detailed notice from us. Both are very good, and stand in the first rank among the scores of arithmetics published in England. The explanations, arrangement and examples, especially in the former book, are generally very good. We will venture, however, to suggest two or three changes to the authors, which we think would render the book better still, and which our experience would make us wish to see universally adopted. The rule for multiplication of decimals given in these books is the old one of counting the decimal places. We think this becomes a rule of thumb. The method ought to be the same as that in multiplication of integers; and it is at once seen by the pupil that as in

multiplying by tens and hundreds, the figures are shifted to the left; so in multiplying by tenths and hundredths, they are shifted to the right. The decimal point is brought down straight, and each line in the working has its meaning; as in the example, multiply $712\frac{35}{100}$ by $15\frac{807}{100}$:—

$$\begin{array}{r} 712\frac{35}{100} \\ 15\frac{807}{100} \\ \hline 3561\frac{75}{100} \\ 7123\frac{5}{100} \\ 569\frac{880}{100} \\ \hline 4\frac{98645}{100} \\ \hline 11260\frac{11645}{100} \end{array}$$

This is more certain to be understood *every time it is done* than the old counting rule, and each line means something. Again, in that schoolmaster's *crux*, the division of decimals, we have in the books before us, the old Case 1, Case 2, and Case 3; and everybody knows the result in an examination. A better method is this, which we indicate briefly. Explain first that you cannot divide until the quantities are of the same kind, and of the same denomination. You cannot divide $2\frac{1}{2}$ by 3 pence, till you have reduced the pounds to pence. Nor can you divide tenths by thousandths, till you have reduced the tenths to thousandths. Hence, to divide $1\frac{375}{1000}$ by $\frac{10025}{100000}$, the dividend must first be expressed in the same denomination as the divisor, namely as ten thousandths; this amounts to marking off as many decimal places in the dividend as there are in the divisor, which is best done by drawing a line after the figure, and then dividing. It is plain that the result is integral until the figures on the right of the line are brought down. It is worth while, perhaps, to give examples of the different cases; the explanation is obvious from what has been already said—

Divide $7\frac{9}{10}$ by $4\frac{308}{1000}$ —

$$\begin{array}{r} 4\frac{308}{1000} \overline{) 7\frac{9000}{1000}} \quad (1\frac{83}{100} \dots \\ \underline{4\frac{308}{1000}} \\ 35920 \\ \underline{34464} \\ 14560 \end{array}$$

Divide $34\frac{79628}{100000}$ by $2\frac{5}{10}$ —

$$\begin{array}{r} 2\frac{5}{10} \overline{) 34\frac{79628}{100000}} \quad (13\frac{91}{100} \dots \\ \underline{25} \\ 97 \\ \underline{75} \\ 229 \\ \underline{225} \\ 46 \end{array}$$

Lastly, the methods of summation by differences and interpolation are essentially arithmetical, and of considerable interest, and we think might be introduced with advantage in the larger work.

The miscellaneous questions at the end of the larger book are not particularly good. They are often tedious, and not sufficiently varied, suggestive, or difficult. Nevertheless, the books are very good, and will teach teachers as well as learners.

J. M. W.

Skandinaviens Coleoptera, synoptiskt bearbetade af G. C. Thomson. Tom. X. 8vo. (Lund, 1868. London: Williams and Norgate.)

THESE are few investigations of more interest to the student of British Natural History than the comparison of our native productions with those of the Scandinavian peninsula, and no descriptive works published on the Continent, a knowledge of which is of greater importance to him, than those of the acute and laborious naturalists of Scandinavia and Denmark. The work done by these

* Alas! that this time-honoured institution of meeting "all hands" once a year should have fallen into disuse. It was a very bond of union.

men is usually of the highest quality, both for carefulness of investigation and clearness of statement; and the great similarity which exists between the faunas and floras of our islands and of the Scandinavian region, enables their work to be used to a certain extent as handbooks by British Naturalists. May their study lead the latter to imitate the Scandinavian mode of work! We are led to these remarks by the receipt of the tenth and concluding volume of Prof. Thomson's descriptive work on the Scandinavian Coleoptera, although this consists almost entirely of corrections, emendations, and additions to the contents of the nine previous volumes, in which the systematic description of those insects was completed. Prof. Thomson's work will be found of the highest value to the British entomologist, inasmuch as a very large proportion of the insects described in it are inhabitants of these islands, and many of the others will probably be discovered hereafter in the north of Scotland. The whole descriptive portion of the book is written in Latin, the characters, although often brief, are admirably drawn up, and the determination of the species is greatly facilitated by the excellent tables both of genera and species given throughout the work. Amended tables, introducing all new forms discovered during the progress of the book, are given in the second part of the ninth and in the tenth volumes. Although it appears under a Swedish title, the only portions of the work written in that language are the notices of localities of occurrence and critical remarks on genera and species, the former, at any rate, requiring little knowledge of Swedish for their comprehension. W. S. D.

Ichneumonologia Suecica, auctore Aug. Emil Holmgren. Tom. II. (Stockholm, 1871. London: Williams and Norgate.)

THIS is a second most important Swedish work, which illustrates in a striking manner the remarks which we made in noticing M. Thomson's "*Skandinavien Coleoptera*." In this the author has commenced a monographic revision of the Swedish members of one of the most difficult families of insects, the Ichneumonidae, which he here treats in an almost exhaustive fashion. We cannot venture to say how far he is correct in his synonymies, or in the reference of supposed species to others as varieties; but he has spared no pains in the preparation of his descriptions, and the student of his book will find no difficulty in understanding precisely what he means. This work, when completed, will be an invaluable aid to the few entomologists who venture upon the study of the Ichneumonidae. W. S. D.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Planet Venus

THIS beautiful planet being now very favourably situated for examination, it may interest many of your astronomical readers if I give a brief description of the markings which have recently been seen on her surface. That these markings are exceedingly difficult objects to detect, even with a powerful telescope and under favourable atmospheric conditions, there is no doubt, and many observers have consequently failed to see them. The late Rev. W. R. Dawes, although possessed of very excellent vision, could never make them out, and it seems that the fact of their existence is doubted at the present time by some observers. At the meeting of the Royal Astronomical Society on November 10 last, "the Astronomer Royal mentioned that Venus was very favourably situated for observation, especially for noticing spots if any existed on her surface, his own experience being that there were no certain markings thereon, which the President corroborated." The opinions of such eminent astronomers should always be carefully considered, and the matter in dispute thoroughly investigated, before a contrary opinion is entertained. In the present case, however, I think that there is a sufficiency of

evidence to prove that markings of various forms exist on the surface of the planet. I am the more particularly induced to say this by having before me upwards of sixty sketches of their appearance, made by experienced observers, who in the making of observations employ telescopes of great power and excellent definition. No doubt the faint cloudlike markings can only be made out after attentive gazing, and then are scarcely visible, though they have been distinctly seen by many observers. It is difficult to account for the fact that Mr. Dawes could not distinguish them, but perhaps the reason may be apparent, if we consider that an observer who is the most successful in the observation of faint companions to double stars, cannot satisfactorily observe the faint markings with which the planet's disc is diversified. Many observations of the spots were made at Rome in 1839—1841, and of six observers those were the most successful who experienced the greatest difficulty in detecting minute companions to large stars.*

With respect to the spots and markings which have recently been examined, it may be said that they are of various forms and degrees of visibility. Some of them are only just perceptible after a long and careful scrutiny of the planet's disc, while others are much more apparent, and distinguishable with less difficulty. Whether or not they are permanent in their form remains to be determined from a comparison of the whole of the observations. Some of the representations of the cloudy spots taken at different dates seem to be somewhat similar in their principal features. Several times that position of the planet's surface immediately adjacent to the terminator has been seen to be interspersed with small bright circular spots, which seem to be analogous to lunar formations. These bright spots have been seen by several of those who have critically examined the planet's appearance. They were seen by Mr. T. H. Buffham on May 4 and May 6, 1868, and Dr. Huggins at the last meeting of the R.A.S. said that "he had occasionally seen dusky spots, but he considers them as very uncertain or illusive. When, however, the crescent was thin and the planet near the earth, he had seen minute points of light on the terminator, which by most observers was described as irregularly indented. He had also noticed that when definition was very good, appearances analogous to those of lunar craters had been seen." Dr. De la Rue had often seen markings on Venus similar in character to those observed on Mars." An observation made by Mr. F. Worthington, with a 13-inch reflector, on June 11 last, confirms the statement made by Dr. Huggins in reference to the bright markings on Venus being similar to objects on the surface of our satellite. He writes, "Definition extremely good. The markings were very clearly seen, and bore a very remarkable resemblance to the craters and inequalities of the moon as seen with a low power, say an opera glass." From the foregoing it would appear to be beyond a doubt that, when the planet is in a crescent form, small bright markings, resembling lunar craters, are perceptible. These objects should be persistently looked for, and when observed the details of their appearance and position duly registered.

That the dark, cloud-like markings are similar to those on the surface of Mars, as stated by Dr. De la Rue, seems also an established fact. Mr. Henry Ormerse has seen several irregular spots on Venus on May 10 last, and he says they were "clear and well-defined, and reminded me very much of those on the planet Mars, as they had much the same appearance." Of course the markings on Mars are much more conspicuous than those visible on Venus, but in their appearance there is no doubt that they are not altogether unlike.

In many of the drawings which I have before me the outlines of the cloudy patches do not terminate abruptly as in the case of the penumbra to solar spots (*maculae*) but seem to fade away into the general brilliancy of the disc. In some of the sketches, however, the boundary of the spots appears to have a well-marked outline. In regard to the terminator, it seems to have a very serrated edge, but in some of the drawings this is not depicted.

Referring again to the coincidence in the appearance of the bright spots of Venus and the craters of the moon, I would draw the attention of your readers to the Rev. T. W. Webb's "*Celestial Objects*," second edition, p. 51, in which there is an observation of interest recorded. WILLIAM F. DENNING

Hollywood Lodge, Cotham Park, Bristol, Nov. 28

* See Webb's "*Celestial Objects*," p. 50. It is there stated that "a very sensitive eye which would detect the spots more readily would be easily overpowered by the light of a brilliant star, so as to miss a very minute one in its neighbourhood."

The Flight of Butterflies

IN the 103rd number of NATURE there are two notices of remarkable butterfly flights in America, and it is asked "Where the yellow butterflies are going?" Mr. R. Spruce, in "Notes on some Insect and other Migrations observed in Equatorial America" (published in the Journal of the Linnean Society, vol. ix. No. 38, read June 6, 1867), has the following curious account of similar flights, which, he says, have also been described by Me-srs. Edwards, Wallace, and Bates: "The first time that I fell in with such a migration was in November 1849, near the mouth of the Xingú, when I was travelling up the Amazon from Pará to Sautareon."

We saw a vast multitude of butterflies flying across the Amazon from the northern to the southern side in a direction from about N.N.W. to S.S.E. They were evidently in the last stage of fatigue. They were all of common white and orange yellow species, such as are bred in cultivated and waste grounds, and having found no matrix whereon to deposit their eggs to the northward of the river (the leaves proper for their purpose having probably been already destroyed or at least occupied by caterpillars) were going in quest of it elsewhere. The very little wind there was, blew from between E. and N.E., therefore the butterflies steered their course at right angles to it; and this was the case in subsequent flights I saw across the Amazon. . . . But the most notable circumstance is that the movement is always southward. . . . Since my return to England I have read Mr. Bates's graphic description of a flight of butterflies across the Amazon, below Obidos, lasting for two days without intermission during daylight. These also all crossed in one direction, from north to south. Nearly all were species of *Callidryas*, the males of which species are wont to resort to beaches, while the females hover on the borders of the forest and deposit their eggs on low-growing, shade-loving *Mimosa*s. He adds, 'the migrating hordes, so far as I could ascertain, are composed only of males.' It is possible, therefore, that in the flights witnessed by myself the individuals were all males—in which case the flights should probably be looked upon, not as migrations, but dispersions, analogous to those of male ants and bees when their occupation is done, and they are doomed by the workers to banishment, which means death. In the case I am about to describe, however, the swarms certainly comprised both sexes, although I know not in what proportion; and their movements were more evidently dependent on the failure of their food.

"In the year 1862 I spent some months at Chandsey, a small village on the desert coast of the Pacific northward of Guayaquil, where one or two smart showers are usually all the rain that falls in a year; but that was an exceptional year, such as there had not been for seventeen years before—with heavy rains all through the month of March, which brought out a vigorous herbaceous vegetation where almost unbroken sterility had previously prevailed. In April swarms of butterflies and moths appeared coming from the East, sucking the sweets of the newly-opened flowers, and depositing their eggs on the leaves, especially of a *Boerhaavia* and of a curious *Amaranth*, until the caterpillars swarmed on every plant. New legions continued to pour in from the East, and finding the field already occupied, launched boldly out over the Pacific Ocean, as Magalhães had done before them, there to find a fate not unlike that of the adventurous navigator. No better luck attended most of the offspring of their predecessors, especially those who fed on the *Boerhaavia*. The shoal of caterpillars advanced, continually westward, eating up whatever to them was eatable, until, on nearing the sea shore and the limit of vegetation, I used to see them writhing over the burning sand in convulsive haste to reach the food and shelter of some *Boerhaavia* which had haply escaped the jaws of preceding emigrants. The explanation of this continual westward movement is not difficult. A few leagues inland, instead of the sandy coast-desert with here and there a tree, we find woods, not very dense or lofty, but where there is sufficient moisture to keep alive a few remnants of the above-mentioned herbs all the year round, and doubtless also of the insects that feed on them. There are also cattle farms. When the rains come on, therefore, they cause as it were a unilateral development of the vegetation from the forest across the open ground, and a corresponding expansion of the insect-life which breeds and feeds upon it."

The whole paper is very interesting, but I have copied only such portions as bear on the question "Where are the yellow butterflies going?"

T. S.-M.

The Origin of Insects

IN an article by Dr. Beale, in your number for Nov. 23, on "One of the Greatest Difficulties of Darwinism," a most extraordinary misconception is stated to be a difficulty. That the pupa state is a modification of the ordinary process of skin-shedding in the Insecta is proved by so many facts, that one cannot understand for a moment how it can possibly be denied, much less how its denial can be made use of as an argument against the doctrine of evolution. Sir John Lubbock pointed out long ago that, in the development of the Insecta, every grade of modification exists between those insects which are gradually developed, each successive ecdysis producing only the slightest possible modifications, and those which undergo a change so complete that it may be likened to the process of metagenesis, as it has been called, which takes place in the Echinodermata.

It is an utter mistake to suppose that any insect is redeveloped during the pupa state. The most perfect instance of metamorphosis is that of the flies (some Diptera). In these the materials out of which the perfect insect is developed are supplied by the breaking up of the muscular system and fat bodies of the larva; but the cellular structures known as the imaginal discs of Weismann are formed in the egg, and persist all through the life of the larva. These, it is true, only form a skin or case in which the fly is developed; but they are really nothing more than a larva skin, formed on the inside of the larva skin in the egg, and detached from it by the subsequent modifications of the larva.

The nervous system undergoes extensive modification in the development of the fly, but it never undergoes degeneration. The mouth organs of the imago, it is true, are not the mouth organs of the larva, nor are they formed by their modification, but they are foreshadowed in the egg before the mouth organs of the larva are formed. It is the mouth organs of the larva which are new formations, not those of the imago. In this most extreme case, the pupa skin is derived directly from the inner layers of the first larval skin, about twelve hours before the creature emerges from the egg. The imaginal skin is likewise derived from cells laid down in contact with the imaginal discs. There is absolutely only a difference in the time at which the successive skins are formed in this and in ordinary ecdysis.

A cimex which undergoes no change of form develops each successive skins from cells laid down within the last integument, and the same process is followed in the development of the fly.

The alimentary canal is likewise undoubtedly formed in a similar manner around that of the larva, and the sexual organs are gradually developed, even from the time when the embryo is enclosed in the egg.

Fritz Müller in his "Facts for Darwin," has shown very conclusively that the larval forms of insects are probably derived from imaginal forms; such seems, without doubt, to be the case with the flies (*Musca*). Every day the difficulties presented by the development of the Insecta to the doctrine of evolution are vanishing. It is extremely probable that insects first emerged from the water with fully formed wings. We have still relics of an aquatic winged insect fauna in the hymenopterous genus discovered by Sir J. Lubbock. We may readily believe the larval forms now existing on the earth are modified forms of originally perfect insects; we know that the larvae are subject to far greater changes of life and far greater struggle for existence than the perfect insects. They are all probably embryonic forms, brought from the egg in a modified state before their perfect development is attained. The same thing is seen in several crustaceans, which are hatched as *Nauplius* forms, whilst all their allies attain the *Zoea* stage in the egg. The existence of mandibulate larvae in insects which in the perfect state have subtoral mouths, is an additional argument in favour of this view. It appears to be either a reversion in the larva to an anterior type, for the earlier types of the Insecta were undoubtedly mandibulate, or it may be an embryonic character, which has never been lost in the egg, modified by reversion or circumstances. This view may appear fanciful, but the aortic arches of a fish undoubtedly exist in the mammalian embryo, and no one can say what changes might take place by reversion in those arches under altered conditions. Teratological embryology goes far to show that the embryo may revert to long anterior types in its development.

I should, however, transgress too far on your valuable space in giving proofs of all that has been put forward. I trust, how-

ever, that even this little may do some good, for it does seem hard, when the labours of men like Fritz Müller, Weismann, and Lubbock, are throwing light on this intricate subject, that darkness should return in the form of manifest misconceptions of well-known phenomena.

Aspect

MR. LAUGHTON'S *aspect* is not only a felicitous word in relation to a plane, but it is susceptible of a wider application than that which he proposes for it, since it expresses a fundamental idea in the theory of surfaces. Every surface has at every point an *aspect*, which is the direction of a normal at that point. This may be regarded as the first property of surfaces, for if we define a surface as that form of extension which has at every part two and only two dimensions, we virtually say that, among all the directions in space that radiate from any point of the surface, there is one and only one perpendicular to all those (infinite in number) that lie within the surface at that point; in other words, that the surface has a normal at every point. A plane is then a continuous surface which has the same *aspect* throughout, the angle of two planes is the measure of their difference in respect of *aspect*; parallel planes (as Mr. Wilson points out) are those which have the same *aspect*, a plane tangent to a surface is one which contains a point of the surface, and has the *aspect* of the surface at that point, and a line tangent to a surface is one that contains a point of the surface, and has a direction which lies within the surface (or is perpendicular to the normal) at that point. Then a straight line tangent to a plane lies wholly in the plane, and if such a line, passing through any assumed point of a plane—rotate about that point—always remaining tangent to the plane, it must sweep every point of the plane, for it will generate a continuous and infinite surface coincident throughout its extent with the plane, and the plane, being continuous, can have no points without this surface. Therefore, a straight line which joins two points of a plane lies wholly in the plane, whence the propositions that a plane is determined by three points, and that the intersection of two planes is a straight line, together with the other elementary theorems of the geometry of space, are readily derived.

The use of *aspect* in the sense now proposed is not absolutely new, as Mr. Proctor (NATURE for October 26) seems to argue. It has the high authority of Sir W. R. Hamilton in his "Lectures on Quaternions" (1853). Thus we read on page 92 (the italics and capitals of the original are preserved):—"A biradial has also a PLANE and an ASPECT, depending on the star or region of infinite space, towards which its plane may be conceived to FACE. . . . When two bi-radials have, in the sense just now explained, the same *aspect*, their planes both facing at the same moment the same star, they may be said to be CONDICTIONAL BIRADIALS. When, on the other hand, they face in exactly contrary ways, and, therefore, have OPPOSITE ASPECTS, they may be called CONTRADICTIONAL. . . . Both these two latter classes may be included under the common name of PARALLEL BIRADIALS, so that the PLANES of any two parallel biradials are either coincident or parallel."

Vaguely, indeed, *aspect* of a plane may be used in the sense Mr. Proctor would assign it, as well as in several other senses. But if we could give it an exact and technical signification, that which is proposed by Mr. Laughton seems to issue directly from the proper meaning of the word; and it is a signification which no other word yet suggested will so easily bear. At present, therefore, it ought to be accepted as the very word that is needed in the re-construction of geometry.

As for *position*, it is pertinent to ask whether anyone would say that parallel planes have the same *position*. The attribute of planes, for which a word is demanded, is precisely that element of position in which parallel planes agree; and the *position* of a plane requires for its determination not that element only, but also some other element whereby the plane shall be distinguished from its parallels.

Permit me, by way of appendix to my too long note, to call the attention of those who are interested in the early teaching of Geometry, which has lately been discussed in your columns, to Dr. Thomas Hill's "First Lessons in Geometry. Facts before Reasoning." (Boston, 1856.)

Cause of Low Barometric Pressure

IN the number of NATURE for July 20, 1871, I find a paper by Ferrel, "On the Cause of Low Barometer in the Polar Regions," &c. The author says that the law which deflects a body to the right in the northern hemisphere and to the left in the southern is not understood by meteorologists, and that it is admitted only when the movement is north and south.

I believe this law is now admitted by almost all meteorologists. The proof of it is the general acceptance of Buys Ballot's law of winds, which states that the wind will always blow towards a barometrical depression, and be deflected to the right in the northern hemisphere.

The most important meteorological works of the last years are based on this principle, as, for example, Buchan's "Mean Pressure and Prevailing Winds," and Mohn's "Storm Atlas." Mr. Mohn states the error which was committed in former times, and gives the expression of the deflecting force (page 17).— $15'' \sin L$ (latitude) per hour. As to Mr. Ferrel's explanation of the low barometer at the poles, I must first state that it is not lowest near the poles. In the northern hemisphere, the lowest pressures are near Iceland and near the Aleutian islands, but northwards they are higher, as the observations of Greenland have shown, as is seen also in the prevalence of N.E. winds in winter at Stykkisholm (Northern Iceland); this would indicate that the pressure to the north and north-west of the last place is higher.

The great barometrical depressions which so often visit Iceland cannot exist at temperatures of some degrees below freezing point. This explains why the barometer cannot be lower at the Arctic Pole than near Iceland in winter; the temperature there must be certainly much lower, even if the pole be surrounded by open water.

It is the low temperature also that explains the course of the Atlantic storms across European Russia (from N.W. to S.E.), as the winter temperature of Siberia is too low to admit the storms. This was already stated by Mr. Mohn, and I can but confirm his opinion. In southern latitudes the barometrical depression seems to increase towards the pole, but do we know enough of these regions to say that the lowest barometer will be at the pole? In the highest southern latitudes attained by Sir James Ross the barometer was a little higher than northward. All that we know about the origin and propagation of barometrical depressions gives us the right to say that pressure cannot be lowest at the south pole, but that, as in the northern latitude, the greatest depression will be found at some distance from the pole, perhaps as far as the Antarctic Circle.

A. WJEIFOKER

Symbols of Acceleration

I WISH to direct the attention of the reviewer of the "New Works on Mechanics," in No. 107 of NATURE, to the following statements which he makes while speaking of Wernicke's book:—"The symbol j is here and throughout the work used to denote an acceleration; for example $j \cdot x$ (sic) is the acceleration parallel to the axis of x . This notation (unfamiliar to English readers) has obvious advantages when the more appropriate language of the differential calculus cannot be employed."

Now I cannot see how the notation is "unfamiliar to English readers," when we have in common use a to denote an acceleration, and a_x an acceleration parallel to the axis of x . Again, though I agree with the reviewer that j , (or the English a_j) has obvious advantages when the more appropriate language of the Differential Calculus cannot be employed, yet it should be remembered that there is a more appropriate notation still, viz., that of Newton's Fluxions, recalled to its proper position in mixed mathematics by Sir W. Thomson (see Thomson's and

Tate's "Nat. Phil.") and beginning to spread, in which $\frac{d^2 x}{dt^2}$

or an acceleration parallel to the axis of x is denoted by $\ddot{x}$. This notation can be employed at all stages of the student's progress, for it is as easy for him to learn that acceleration parallel to the axis of x , actual acceleration in the path, &c., are denoted by $\ddot{z}$, $\ddot{s}$, &c., as to make himself acquainted with Wernicke's symbols. Afterwards, when studying the Differential Calculus, he may be told the name of the notation, and have his knowledge of it enlarged, but he will never need to unlearn it; on the contrary, he will

* See also my paper "On Barometrical Amplitudes," in the *Journal of the Austrian Meteorological Society*, 1871, No. 10.

find its service increase in importance as he makes his way into the highest parts of the subject.

Of course no attempt is here made to attack D-ism, but to state that it and Dot-ism have their proper spheres, the latter generally, with more or less appropriateness, throughout the whole realm of functions, the former in the realm of motion, where the functions are functions of *t*—the sway over which realm was originally given to it by Newton, and acknowledged, as I have been told, by the D-ist Lagrange.

THOMAS MUIR

Occurrence of the Eagle Ray

A DOUBLE-SPINED specimen of the eagle ray (*Myliobatis aquila*), taken in Torbay on the 1st Nov., has been presented to this museum by Mr. Frank Gosden, fish dealer, High Street, Exeter. Its dimensions are as follows:—Breadth across the fins, 2ft. 3½ in.; length from snout to the base of the spines, 1ft. 7½ in.; total length from snout to extremity of the tail, 3ft. 6½ in.

W. S. M. D'URBAN, Curator

Albert Memorial Museum, Exeter

Deep Sea Dredging

WHILE winter allows of time for complete arrangements to be made in anticipation of dredging weather, will you permit me to raise the question of the conditions under which our knowledge of the natural history of the sea may be most readily extended?

As a rule, yacht owners object to the fatigue and dirt of dredging, but as we have the successful example of the *Norna*, may we not hope that other yachts may further the cause of science, if assistance in the way of instruction or apparatus be afforded to them by those having the necessary experience and means?

The idea of now urging the question is not mine alone, but is entertained by many ardent naturalists who are much in favour of a skilful search of our seas at home, as well as of the Mediterranean and other distant and almost untried seas.

Your pages have often borne witness to the interest and importance attaching to marine zoology, and if men of practical experience, such as Carpenter, W. Thomson, Marshall Hall, &c., will indicate the best localities for search and the best measures to adopt, we may hope that others may follow in their steps, and that the large aquaria now built and building will be supplied, as only private zeal and enterprise can compass, with new and rare specimens from deep waters.

T. H. HENNAH

Milton House, Clarence Street, Brighton, Dec. 5

The Solar Halo

THE solar halo of the morning of the 13th ult. described in your last number as seen near, and at about thirty miles from, Durham, and which Prof. A. S. Herschel conjectures may have been seen from more distant stations, was visible here.

I first saw it at about 8 A.M., when it appeared as the arc of a circle, with a very short portion of an inverted arc touching it at the vertex—the sun itself being hidden by a bank of cloud, from behind which issued several radiating spikes. Shortly after half-past nine this halo had disappeared, except a small portion at the point of contact of the two arcs, vertically over the sun, which appeared like a bright elongated patch, forked at each end, and projected not on mist, but on blue sky, and tinged with dull prismatic colours, which were most strongly marked in the inverted arc, in which the red or orange was downwards, or on the outside of the circle. I then suddenly caught sight of a second halo, of much greater radius than the first—visible through perhaps 130° or 140° of arc, above, and to the right of, the sun, projected on the clear blue sky, but so faintly that it might easily have been missed. This outer circle exhibited the prismatic colours with a purity and delicacy that I have never before seen in halos, and which was quite different to the ordinary dull, muddy colours. In fact, it had just the appearance of a very faint and narrow rainbow, the red being inside, and the blue outside the circle. I was shortly after able to borrow a sextant, and measured the distance from the sun to the bright patch and the outer circle, which appeared respectively 21° 40' and 43° 20'; but they were already growing so faint that I was unable to do this with much precision. Except the bright patch before named, I did not observe any appearance of "mock-sun."

Cardiff, Dec. 4

GEO. C. THOMPSON

ON THE ZIPHIOD WHALES

THE peculiar division of Cetaceans to which the term "Ziphioid" is now commonly applied, from one of the earliest known forms, *Ziphius* of Cuvier, is in many respects one of the most interesting of the order. They form a very compact group, united closely together by the common possession of very definite structural characters, and as distinctly separated from all other groups by equally definite characters.

With the singular exception of *Hyperoodon rostratus* (the structure and habits of which species are as well known, perhaps, as those of any other cetacean), no specimen of the group had ever come under the notice of any naturalist up to the commencement of the present century. Since that time, however, at irregular intervals, in various and most distant parts of the world, solitary individuals have been caught or stranded, now amounting to nearly thirty, these being by some naturalists referred to upwards of a dozen distinct species and to very nearly as many genera. No case is recorded of more than one of these animals having been observed at one place at a time, and their habits are almost absolutely unknown. Their very presence in the ocean seems to pass unnoticed and unsuspected by voyagers, and even by those whose special occupation is the pursuit and capture of various better known and more abundant cetaceans, until one of the accidental occurrences just alluded to reveals the existence of forms of animal life of considerable magnitude, and at least sufficiently numerous to maintain the continuity of the race.

This comparative rarity at the present epoch contrasts greatly with what at one time obtained on the earth, especially in the period of the crag formations, and leads to the belief that the existing ziphioids are the survivors of an ancient family which once played a far more important part than now among the cetacean inhabitants of the ocean, but which have been gradually replaced by other forms, and are themselves probably destined ere long to share the fate of their once numerous allies or progenitors.

The Ziphioid whales belong to the great primary division or sub-order of the Odontocetes or Toothed whales, as distinguished from the Whalebone whales. They are allied on the one hand to the Cachalots or Sperm whales, and on the other to the true Dolphins and Porpoises, but more nearly to the former than the latter. They are animals varying between fifteen and thirty feet in length, and in external characters very closely resemble each other, all having small pointed snouts or "beaks," small rounded or oval pectoral fins or "flippers," a comparatively small triangular dorsal fin, situated considerably behind the middle of the back, and a single "blowhole" of concentric form, situated in the middle of the top of the head. One of their most obvious characteristics, distinguishing them from the true dolphin, is the complete absence of teeth (except occasionally a few mere rudiments concealed in the gum) in the upper jaw, while in the lower jaw there is usually but a single pair, which in some species may be greatly developed and project like tusks from the mouth, though sometimes even these are rudimentary and covered up by the gum, so that the animal is practically toothless. In addition to these external and easily-recognised characters, there are others connected with the skeleton and internal organs which separate them still more trenchantly from the other members of the order. Their food appears

* "J'appliquerai au genre dont elle (a skull found on the shore of the Mediterranean) devient le premier type, le nom de *Ziphius*, employé par quelques auteurs du moyen âge (Voyez Gesner l. p. 209) pour un cétacé qu'il n'ont point déterminé" (Cuvier, "Ossuaires fossiles"). According to strict rules of priority "*Hyperodontoid*" would be the more correct term, as *Hyperoodon* was the first genus of the group distinctly characterised; but as the name is erroneous in its signification, it will be better to keep to the more generally adopted and less objectionable term of "*Ziphioid*," first applied by Gervais. The group is equivalent to Eschricht's "*Rhynchoceti*."

to consist almost exclusively of cephalopods, or cuttlefish-like animals.

One of the greatest obstacles to acquiring a more accurate knowledge of this group is the excessively confused state of the nomenclature of the different animals of which it is composed. Nearly every single specimen that has been met with has been described under a different name, and before their characters and affinities were understood they were banded about from one genus to another, even different individuals of the same species having been placed by systematists in different genera, until it has become almost impossible to write or speak of any of them, without the fear of inadvertently adding to the perplexity of those that come after, by adopting and perpetuating some ill-chosen or incorrect term.

In a valuable recent memoir on the subject by Prof. Owen,* the difficulty is disposed of in a very summary manner by uniting all the known forms, both recent and extinct (with the exception of *Hyperoodon*), under the generic name of *Ziphius*. This proceeding, at all events, has the merit of running no risk of adding to the confusion of nomenclature, caused by hasty or ill-defined generic subdivisions, founded on imperfect or fragmentary knowledge of the animal described. But, however great our admiration may be for this strong-handed resistance to the passion for name-coining, which is fast rendering the study of zoology almost an impossibility, it must not lead us to overlook well-marked structural characteristics by which certain small groups of species are allied together, and differentiated from others, whether we call them genera or by any other term.

In a paper recently presented to the Zoological Society (read Nov. 7), I have given reasons for my belief that the species of ziphioids at present known (I refer only to those now existing, not to the extinct forms), may be naturally arranged by certain structural characters, especially the conformation of the skull and teeth, into four groups; and as, so far as is yet known, these are not united by intermediate forms, they may, I think, be considered as generic, though of course this is a subject upon which the judgment of different zoologists may differ. This arrangement does not differ from that adopted by several other zoologists, who have specially studied the animals of this group, but the characteristics of each section or genus have not hitherto been clearly defined.

It is not my present purpose to enter into the details of these characteristics, for which I must refer to the above-mentioned communication, but to give a short summary of the known zoological facts relating to the different animals of which each is composed, so that a general idea may be gained of our present state of knowledge of the whole group.

1. Genus *Hyperoodon*, Lacépède.—This genus differs from the rest in having a very prominent convex "forehead" as it appears externally, though really corresponding to the lower part of the face of other animals, supported by strong bony crests on the maxilla, and below which the small pointed snout projects, something like the neck of a bottle from its shoulder, hence the name "Bottle-nose" often applied to these animals, in common with various other cetaceans. The common *Hyperoodon* (*H. rostratus*) is, as before mentioned, one of the best known of cetaceans, being a regular visitor to our coasts, and having been frequently described and figured by naturalists who have had opportunities of observing it in a fresh state. Skeletons, moreover, are to be seen in nearly every considerable osteological museum. The first really good description and figure is that of John Hunter, founded on an individual which was caught in the Thames near London Bridge, in the year 1783, and the skeleton of which still hangs in the great hall of the Museum of the Royal College of Surgeons. The figure of

the animal appears in the Philosophical Transactions for 1787. Among the numerous subsequent contributions to the knowledge of the structure and natural history of this species, the monographs of Vrolik and of Eschricht are of especial importance.

The common *Hyperoodon* attains the length of twenty to twenty-five feet. It has no functional teeth, the only two which it possesses are quite small and buried in the gum at the front end of the lower jaw, but the palate is beset with numerous minute horny points. As in many other whales in which the teeth are either absent or very rudimentary when adult, it possesses a complete set at a very early period of its growth, but the majority of these disappear even before birth. Judging by the contents of the stomach of the captured specimens, their food consists of several kinds of squid and cuttlefish, and not of true fish; they are, therefore, not the enemies to fishermen that some have supposed them, but rather the reverse, for the cuttles, of which they destroy great quantities, are themselves voracious fish-eaters. In geographical range this species is limited to the North Atlantic, having been found both on the American and European coasts, extending as far north as Greenland, but its southern limit has not been accurately determined; it has, however, never been known to enter the Mediterranean. Within this range it is migratory, spending the summer in the Polar seas and the winter in the Atlantic, and it is chiefly on its passage northwards in the spring and southwards in the autumn that it visits our shores. It happens almost every year that in the last-named season one or more are stranded on some part of the extensive coastline of the British Isles; usually a female accompanied by a young one, seeking probably for food in too shallow water, are cut off by the retreating tide from their chance of regaining the open sea. In these cases it appears that it is the less experienced younger animal which gets into danger, and is then rarely abandoned by the old one, who thus falls a victim to the strength of the maternal instinct so largely developed in the cetacea. The old males are apparently more wary, and rarely approach the shore near enough to be taken. They are never seen in herds or "schools" like so many of their congeners, but always either singly or in pairs.

Another animal, allied to *Hyperoodon rostratus* but of larger size, being fully thirty feet in length, and of heavier proportions, has been occasionally met with in the North Seas, and is generally supposed to be another species of the same genus (*H. latifrons*), though some naturalists have maintained that it is nothing more than the old male of the former.

II. Genus *Ziphius*.—The type of this genus is *Z. cavirostris* of Cuvier, founded on an imperfect skull picked up in 1804 on the Mediterranean coast of France, near Fos, Bouches-du-Rhône, and described and figured in the "Ossements Fossiles." It was at first supposed to be a fossil, but has since been proved to belong to a species still living in the Mediterranean, and there is no evidence that the skull is of ancient date.

2. An animal of the same species was afterwards taken on the coast of Corsica; its external characters are described and figured by Doumet in the *Revue Zoologique*, v. 1842, p. 208, and its skeleton is preserved at Cete.

3. A third specimen was stranded near Aresquiers, Hérault, South France, in 1850; the skull, which is now in the Museum at Paris, has been described by Gervais and Duvernoy (*Annales des Sciences Naturelles*, 3 series, 1850 and 1851).

4. In the Museum of Arachon is a skull found on the beach at Lanton, Gironde, West France, in 1864, and described and figured by Fischer, in the *Nouvelles Archives du Muséum*, tome 3, 1867.

5. A complete skeleton of an adult animal is mounted in the Anatomical Museum of the University of Jena. This was obtained at Villa Franca in 1867 by Prof. Haeckel, but has not yet been described.

6. In the Museum of

* British Fossil Cetacea from the Crag. Palæontological Society, vol. xxiii., 1870.

the University of Louvain is a skull of an animal of this genus, brought from the Cape of Good Hope, of which a description has been published by Prof. Van Beneden, under the name of *Ziphius indicus* (Mem. de l'Acad. Roy. de Belgique, coll. in 8vo, 1863). 7. A very similar skull in the British Museum, also from the Cape of Good Hope, has been described by Gray (Proc. Zool. Soc. 1865, p. 524) by the name of *Petrorhynchus capensis*. 8. A complete specimen of a young male, thirteen feet long, was taken near Buenos Ayres in 1865, and is the subject of an elaborate memoir by Burmeister (Annales de Museo Publico de Buenos Aires, Vol. i. p. 312, 1869), accompanied by detailed figures of external characters, skeleton, and some of the viscera. The specimen was first named in a preliminary notice *Ziphiorhynchus erytrodon*, but subsequently described as *Epidodon australis*.

Such are the materials upon which our knowledge of the genus *Ziphius* is based. For the present it is impossible to determine whether the differences that have been noticed in the above-mentioned specimens are the result of age, sex, or individual peculiarity, or whether they denote specific distinctions. The remains that are preserved indicate in every case an animal of rather smaller size than the *Hyperoodon*.

III.—Genus *Mesoplodon*, Gervais. It is not without some hesitation that I assign this designation to the present well-marked section, as it is extremely difficult to determine which of the numerous names which have been given to it by various authors should have the preference. The type-species of the group, Sowerby's whale, has had no less than eleven generic appellations given to it since its discovery in 1804, viz., *Physeter*, *Delphinus*, *Heterodon*, *Dioxon*, *Aodon*, *Nodus*, *Delphinorhynchus*, *Micropteron*, *Mesoplodon*, *Mesodiodon*, and *Ziphius*! Many of these names had to be abandoned almost as soon as they were bestowed, as their authors had overlooked the fact that they had been previously appropriated to other members of the animal kingdom. To give a full account of the entangled literary history of the genus would occupy too much space for the present communication, so I will content myself with enumerating the specimens which are referable to it, as far as they are known to me, existing in various museums, from which some idea of the frequency of occurrence and of the geographical distribution of the animals will be obtained. They are rather more numerous than those of *Ziphius*.

1. An imperfect skull in the University Museum, Oxford, from an animal (a male) sixteen feet long, obtained on the coast of Elginshire, figured and described by Sowerby (*British Miscellany*, p. 1, 1804) under the name of *Physeter bidens*, but to which the specific name of *Sowerbyi* has since been generally attached. (This is *Delphinus* (*Heterodon*) *Sowerbensis* of De Blainville, Nouv. Dict. d'Hist. Nat., t. ix., 1817, Second edition; *D. Sowerbyi* Desmarest, Mammalogie, 1822.) 2. A skull in the Paris Museum from a female specimen fifteen feet long, stranded at Havre, Sept. 9, 1825, described by De Blainville (Nouv. Bulletin. Sc. t. iv., 1825) as the "Dauphin du Dale," by Cuvier as *Delphinus* (*Delphinorhynchus*) *micropterus*, and afterwards by a variety of other names, but now generally considered to be specifically identical with the first mentioned. 3. A complete skeleton in the Brussels Museum from a young specimen stranded at Ostend, August 31, 1835. 4. A skull and part of skeleton in the Museum at Caen from Sallenelles, Calvados, North France, 1825. 5. Mutilated skull in the Museum of the Royal Dublin Society, from an animal fifteen feet long, stranded in 1864 in Bandon Bay, Kerry, Ireland. 6. Another skull and some bones in the same museum from a second specimen from the same locality, in 1770. 7. A lower jaw in the Christiana Museum, from the Coast of Norway. 8. A skull in the University Museum, Edinburgh, of unknown origin. (I am indebted to Prof. Van Beneden for information about

this specimen, which has not hitherto been recorded.) All these appear to belong to one species. The adult males have a single triangular compressed tooth on each side, rather in front of the middle of the lower jaw, which projects beyond the lip like a tusk, working against a hard callous pad in the upper jaw. In the specimen from Calvados, a group of barnacles had attached themselves to the outer surface of the tooth. 9. In the British Museum is a skull received from the Cape of Good Hope, with teeth in a similar situation, but developed to such an extent as to pass (curving upwards, backwards, and finally inwards) all round the upper jaw, and actually to meet above, preventing the mouth from opening beyond a very few inches at most. It is very difficult to imagine how the animal could have lived and obtained food in this condition, and it might well be supposed to be an individual deformity, but Mr. E. Layard has shown me a tooth of another individual having exactly the same conformation, and being upwards of a foot in length. To this species the name of *Layardii* has been applied by Dr. Gray. 10. An animal probably of the same species, but with the tooth much less developed (? a female), was very lately stranded at Little Bay, about six miles from Sydney, and its skeleton is now in the Australian Museum. 10. In the Museum at Caen there is another skull, from an animal caught in the entrance of the Channel about 1840, which appears to belong to a different species from those ordinarily found on our coasts, as the compressed tooth is placed nearer the apex of the jaw. 12. A skull in the Museum at Paris, remarkable for the peculiar form of the lower jaw, and of the heavy massive tooth which it supports, obtained from the Seychelle Islands, has received the specific name of *densirostris*, and very recently a complete skeleton of the same (13), obtained by Mr. Krefft from Lord Howe's Island, has been added to the Sydney Museum, already rich in skeletons of rare Cetaceans. Lastly (14), in the Museum at Wellington, New Zealand, is a skull and some bones of an animal, nine feet long, which was killed in Titai Bay, Cook's Strait, January 1866, and figured by Dr. Hector in the "Transactions of the New Zealand Institute," vol. iii., part xv., of which the conformation of the skull shows that it is a member of this group; but the single compressed tooth in the lower jaw is situated farther forwards than in any other known species, thus completing the series of different positions in the side of the ramus occupied by the developed teeth, and proving its small value as a generic character.

IV.—*Berardius*, Duvernoy. This genus was founded by Duvernoy upon a skull received at the Museum of Paris in 1846, having been obtained from an animal stranded in Akaroa Harbour, New Zealand. In the name of *Berardius Arnuxi* conferred upon it by Duvernoy, the captain of the French corvette, *Le Rhin*, Bérard, and the surgeon, Arnoux, who jointly presented the specimen, with some others of considerable interest to the Museum, are commemorated in zoological literature.

Only three other specimens of this animal have since been seen, and all on the coasts of New Zealand:—One in 1862, embayed in Porirua Harbour, was converted into oil, and can only be conjectured to have been a *Berardius* by its dimensions, and a slight description published by Mr. Knox. In January 1870 another was taken in Worser's Bay near the entrance to Port Nicholson, and its skull and some bones were preserved for the Wellington Museum; and, lastly, a specimen of this fine animal, which is thirty feet long, and, after *Hyperoodon latifrons*, the largest of the group, ran aground on the beach near New Brighton, Canterbury, on the 16th of December, 1868, where it fortunately came under the notice of Dr. Julius Haast, F.R.S., the energetic and able geologist, and Curator of the Museum at Christ Church. The details of its capture are given by Dr. Haast in the Proceedings of the Philosophical Institute of Canterbury,

New Zealand, May 5, 1869, and also in the "Annals and Mag. Nat. Hist." October 1870.

The skeleton of this animal has been lately placed among the fine series of Cetaceans in the Museum of the Royal College of Surgeons, thanks to the extremely liberal desire of Dr. Haast that it should be made as available as possible for scientific examination, comparison, and description, and to the generosity of Mr. Erasmus Wilson, F.R.S., a member of the Council of the College, in providing the means of adding it to the collection without expense to the Institution. A detailed and fully illustrated description of this skeleton formed part of the communication to the Zoological Society alluded to above, and will appear shortly in the "Transactions." All the characters of the skeleton agree generally with those of the other Ziphioids, but it appears in some respects to be a less specialised form, approaching somewhat nearer to the true dolphins, while *Hyperoodon* is at the other extremity of the series, being modified in the direction of the sperm whales. It has two teeth on each side of the lower jaw, situated near the front end or symphysis, which show nearly the same characteristic and peculiar structure as that described by Mr. Ray Lankester in the teeth of *Mesoplodon Sowerbyi*. The skull is far more symmetrical than in any other member of the group, and wants the great maxillary crests of *Hyperoodon*, and the dense ossification of the rostrum found in so many of the others. The cervical region is comparatively long, with the majority of its vertebrae free, the dorsals and ribs are ten in number, the lumbar and caudals thirty-one, making forty-eight in all. Viewing the skeleton as a whole, the most striking feature is the small size of the head compared with the great length of the vertebral column, and the massiveness of the individual bones, especially of the lumbar and anterior caudal vertebrae. It presents in this respect a remarkable contrast to the sperm whale, which hangs near it in the museum, though agreeing generally with the other Ziphioids. As before mentioned, it is thirty feet in length, and, as Dr. Haast was able to observe, it agrees with its congeners in the nature of its food, for its stomach was found to contain about half a bushel of the horny beaks of cephalopods. The colour of the whole animal when fresh was of a deep velvety black, with the exception of the lower portion of the belly, which was greyish.

Extinct Ziphioids.—To the circumstance of the extreme density of the rostral portion of the skull of certain Ziphioids, owing to the firm ossification of the mesethmoid cartilage and its coalescence with the surrounding bones (the maxilla, premaxilla, and vomer) our knowledge of many of the ancient members of this group of whales is due. When all other portions of the skeleton have yielded to the destructive influence of time, these rostra, generally in the form of elongated and somewhat flattened cylinders, worn and eroded by the action of water, gravel, and sand, occasionally come to light to attest the presence of a former world of oceanic life. A few teeth also have been found which would appear to be referable to these same animals. The localities in which these occur in England are the Red Crag deposits of Suffolk. They are still more abundant, and in a much more perfect condition in the beds of corresponding age in the neighbourhood of Antwerp, which have fortunately been laid bare by the excavations made in the defensive works of that city. A magnificent series of these fossils containing many new forms has recently been added to the Brussels Museum, but until M. le Vicomte Du Bus, the accomplished late Director of the Museum, has completed the great task he has undertaken of determining and describing them, they are as little available for zoological science as if they still lay

Where fathom line could never touch the ground.

W. H. FLOWER

CONTINUITY OF THE FLUID AND GASEOUS STATES OF MATTER *

WHEN we find a substance capable of existing in two fluid states different in density and other properties, while the temperature and pressure are the same in both; and when we find also that an introduction or abstraction of heat without change of temperature or of pressure will effect the change from the one state to the other; and also find that the change either way is perfectly reversible, we speak of the one state as being an ordinary gaseous and the other as being an ordinary liquid state of the same matter; and the ordinary transition from the one to the other we would designate by the terms boiling, or condensing; or occasionally by other terms nearly equivalent, such as evaporation, gasification, liquefaction from the gaseous state, &c. Cases of gasification from liquids, or of condensation from gases, when any chemical alteration accompanies the abrupt change of density, are not among the subjects proposed to be brought under consideration in the present paper. In such cases I presume there would be no perfect reversibility in the process; and if so, this would of itself be a criterion sufficing to separate them from the proper cases of boiling or condensing at present intended to be considered. If now the fluid substance, in the rarer of the two states—that is, in what is commonly called the gaseous state—be still further rarefied, by increase of temperature or diminution of pressure, or be changed considerably in other ways by alterations of temperature and pressure jointly, without its receiving any abrupt collapse in volume, it will still, in ordinary language and ordinary mode of thought, be regarded as being in a gaseous state. Remarks of quite a corresponding kind may be made in describing various conditions of the fluid (as to temperature, pressure, and volume), which would in ordinary language be regarded as belonging to the liquid state.

Dr. Andrews (Phil. Trans. 1869) has shown that the ordinary gaseous and ordinary liquid states are only widely separated forms of the same condition of matter, and may be made to pass into one another by a course of continuous physical changes presenting nowhere any interruption or breach of continuity. If we denote geometrically all possible points of pressure and temperature jointly by points spread continuously in a plane surface, each point in the plane being referred to two axes of rectangular coordinates, so that one of its ordinates shall represent the temperature, and the other the pressure denoted by that point; and if we mark all the successive boiling- or condensing-points of temperature and pressure as a continuous line on this plane; this line, which may be called the boiling line, will be a separating boundary between the regions of the plane corresponding to the ordinary liquid state and those corresponding to the ordinary gaseous state. But, by consideration of Dr. Andrews's experimental results, we may see that this separating boundary comes to an end at a point of pressure and temperature, which, in conformity with his language, may be called the critical point of pressure and temperature jointly; and we may see that, from any ordinary liquid state to any ordinary gaseous state, the transition may be effected gradually by an infinite variety of courses passing round outside the extreme end of the boiling line.

Now it will be my chief object in the present paper to state and support a view which has occurred to me, according to which it appears probable that, although there be a practical breach of continuity in crossing the line of boiling-points from liquid to gas or from gas to liquid, there may exist in the nature of things a theoretical continuity across this breach, having some real and true significance. This theoretical continuity, from the ordinary liquid state to the ordinary gaseous state, must be supposed to be such as to have its various courses passing through conditions of pressure, temperature, and volume in unstable equilibrium for any fluid matter theoretically conceived as homogeneously distributed while passing through the intermediate conditions. Such courses of transition, passing through unstable conditions, must be regarded as being impossible to be brought about throughout entire masses of fluids dealt with in any physical operations. Whether in an extremely thin lamina of gradual transition from a liquid to its own gas, in which it is to be noticed the substance would not be homogeneously distributed, conditions may exist in a stable state, having some kind of correspondence with the unstable conditions here theoretically conceived,

* "Considerations on the abrupt change at boiling or condensing in reference to the Continuity of the Fluid State of Matter," by Professor James Thomson, LL.D., Queen's College, Belfast, read before the Royal Society, Nov. 16, 1871.

will be a question suggested at the close of this paper in connection with some allied considerations.

It is first to be observed that the ordinary liquid state does not necessarily cease abruptly at the line of boiling-points, as it is well known that liquids may with due precautions be heated considerably beyond the boiling temperature for the pressure to which they are exposed. This condition is commonly manifested in the boiling of water in a glass vessel by a lamp placed below, when the temperature of the internal parts of the water, or, in other words, of the parts not exposed to contact with gaseous matter, rises considerably above the boiling-point for the pressure, and the water boils with bumping.* At this stage it becomes desirable to refer to Dr. Andrews's diagram of curves, showing his principal results for carbonic acid, and to consider carefully some of the remarkable features presented by those curves. In doing so, we have first, in the case of the two curves for $13^{\circ} \cdot 1$ and $21^{\circ} \cdot 5$ which pass through the boiling interruption of continuity, to guard against being led by the gradually bending transition from the curve representing obviously the liquid state into the line seen rapidly ascending towards the curve repre-

senting obviously the gaseous state, to suppose that this curved transition is in any way indicative of a gradual transition from the liquid towards the gaseous state. Dr. Andrews has clearly pointed out, in describing those experimental curves, that the slight bend at about the commencement of the rapid ascent from the liquid state is to be ascribed to a trace of air unavoidably present in the carbonic acid; and that if the carbonic acid had been absolutely pure, the ascent from the liquid to the gaseous state would doubtless have been quite abrupt, and would have shown itself in his diagram by a vertical straight line, when we regard the co-ordinate axes for pressures and volumes as being horizontal and vertical respectively. Now in the diagram here submitted, the continuous curves (that is to say, those which are not dotted) are obtained from Dr. Andrews's diagram with the slight alteration of substituting, in accordance with the explanations just given, an abrupt meeting instead of the curved transition between the curve for the liquid state and the upright line which shows the boiling stage. Looking to either of the given curves which pass through boiling, and, for instance, selecting the curve for $13^{\circ} \cdot 1$, we perceive, from what has been said as to

the conditions to which boiling by bumping is due, that for the temperature pertaining to this curve the liquid state does not necessarily end at the boiling pressure for this temperature; and that thus in the diagram the curve showing volumes for the liquid state must not cease at the foot of the upright line which marks the boiling stage of pressure, but must extend continuously, for some distance at least, into lower pressures in some such way as is shown by the dotted continuation from *a* to *b*. But now the question arises, Does this curve necessarily end at any particular point *b*? We know that the extent of this curve in the direction from *a* towards or past *b*, along which the liquid volume will continue to be represented before the explosive or bumping change to gas occurs, is very variable under different circumstances, being much affected by the presence of other fluids, even in small

quantities, as impurities in the fluid experimented on, and by the nature of the surface of the containing vessels, &c.

The consideration of the subject may be facilitated, and aid towards the attainment of clear views of the mutual relations of temperature, pressure, and volume in a given mass of a fluid may be gained, by actually making, or conceiving there to be made, for carbonic acid, from the data supplied in Dr. Andrews' experimental results, a solid model consisting of a curved surface referred to three axes of rectangular co-ordinates, and formed so that the three co-ordinates of each point in the curved surface shall represent, for any given mass of carbonic acid, a temperature, a pressure, and a volume which can co-exist in that mass. It is to be noticed here that in his diagram of curves the results for each of the several temperatures experimented on are combined in the form of a plane-curved line referred to two axes of rectangular co-ordinates, one of each pair of co-ordinates representing a pressure, and the other representing the volume corresponding to that pressure at the temperature to which the curve belongs. Now to form a model such as I am here recommending, and have myself made, Dr. Andrews' curved lines are to be placed with their planes parallel to one another, and separated by intervals proportional to the differences of the temperatures to

* It has even been found by Dufour (Bibliothèque Universelle, Archives, year 1861, vol. xii. "Recherches sur l'Ébullition des Liquides") that globules of water floating immersed in oil, so as neither to be in contact with any solid nor with any gaseous body, may, under atmospheric pressure, be raised to various temperatures far above the ordinary boiling-point, and occasionally to so high a temperature as 173°C . without boiling. On this subject reference may also be made to the important researches of Donny, "Sur la Cohésion des Liquides et sur leur Adhérence aux Corps solides," *Ann. de Chimie*, year 1846, 3rd ser. vol. xvi. p. 167, — July 28, 1871.

which the curves severally belong, and with the origins of co-ordinates of the curves situated in a straight line perpendicular to their planes, and with the axes of co-ordinates of all of them parallel in pairs to one another, and then the curved surface is to be formed so as to pass through those curved lines smoothly or evenly.* The curved surface so obtained exhibits in a very obvious way the remarkable phenomena of the voluminal conditions at and near the critical point of temperature and pressure, in comparison with the voluminal conditions throughout other parts of the range of gradually varying temperatures and pressures to which it extends, and even throughout a far wider range into which it can in imagination be conceived to be extended. It helps to afford a clear view of the nature and meaning of the continuity of the liquid and gaseous states of matter. It does so by its own obvious continuity throughout its expanse round the end of the range of points of pressure and temperature where an abrupt change of volume can occur by boiling or condensing. On the curved surface in the model Dr. Andrews' curves for the temperatures $13^{\circ} \cdot 1$, $21^{\circ} \cdot 5$, $31^{\circ} \cdot 1$, $32^{\circ} \cdot 5$, $35^{\circ} \cdot 5$ and $48^{\circ} \cdot 1$ Centigrade, which afford the data for its construction, may with advantage be all shown drawn in their proper places. The model admits of easily exhibiting in due relation to one another a second set of curves, in which each would be for a constant pressure, and in each of which the co-ordinates would represent temperatures and corresponding volumes. It may be used in various ways for affording quantitative relations interpolated among those more immediately given by the experiments.

We may now, aided by the conception of this model, return to the consideration of continuity or discontinuity in the curves in crossing the boiling stage. Let us suppose an indefinite number of curves, each for one constant temperature, to be drawn on the model, the several temperatures differing in succession by very small intervals, and the curves consequently being sections of the curved surface by numerous planes closely spaced parallel to one another and to the plane containing the pair of co-ordinate axes for pressure and volume. Now we can see that, as we pass from curve to curve in approaching towards the critical point from the higher temperatures, the tangent to the curve at the steepest point or point of inflection is rotating, so that its inclination to the plane of the co-ordinate axes for pressure and temperature, which we may regard as horizontal, increases till, at the critical point, it becomes a right angle. Then it appears very natural to suppose that in proceeding onwards past the critical point, to curves successively for lower and lower temperatures, the tangent at the point of inflection would continue its rotation, and the angle of its inclination, which before was acute, would now become obtuse. It seems much more natural to make such a supposition as this than to suppose that in passing the critical point from higher into lower temperatures the curved line, or the curved surface to which it belongs, should break itself asunder, and should come to have a part of its conceivable continuous course absolutely deficient. It thus seems natural to suppose that in some sense there is continuity in each of the successive curves by courses such as those drawn in the accompanying diagram as dotted curves uniting continuously the curves for the ordinary gaseous state with those for the ordinary liquid state.

The physical conditions corresponding to the extension of the curve from *a* to some point *b* we have seen are perfectly attainable in practice. Some extension of the gaseous curve into points of temperature and pressure below what I have called the boiling, or condensing line, as for instance some extension such as from *c* to *d* in the figure, I think we need not despair of practically realising in physical operations. As a likely mode in which to bring steam continuing gas us to points of pressure and temperature at which it would collapse to liquid water if it had any particle of liquid water present along with it, or if other circumstances were present capable of affording some apparently requisite conditions for enabling it to make a beginning of the change of state,† I would suggest the ad-

* For the practical execution of this, it is well to commence with a rectangular block of wood, and then carefully to pare it down, applying, from time to time, the various curves as templates to it; and proceeding according to the general methods followed in a shipbuilder's modeling room in cutting out small models of ships according to curves laid down on paper as cross sections of the required model at various places in its length.

† The principle that "the particles of a substance, when existing all in one state only, and in continuous contact with one another, or in contact only under special circumstances with other substances, experience a difficulty of making a beginning of their change of state, whether from liquid to solid, or from liquid to gaseous, or probably also from solid to liquid," was proposed by me, and, so far as I am aware, was first announced in a paper by

mitting speedily of dry steam nearly at its condensing temperature for its pressure (or, to use a common expression, *nearly saturated*) into a vessel with a piston or plunger, all kept hotter than the steam, and then allowing the steam to expand till by its expansion it would be cooled below its condensing point for its pressure; and yet I would suppose that if this were done with very careful precautions the steam might not condense, on account of the cooled steam being surrounded entirely with a thin film of superheated steam close to the superheated containing vessel. The fact of its not condensing might perhaps best be ascertained by observations on its volume and pressure. Such an experiment as that sketched out here would not be easily made, and unless it were conducted with very great precautions, there could be no reasonable expectation of success in its attempt; and perhaps it might not be possible so completely to avoid the presence of dust or other dense particles in the steam as to make it prove successful. I mention it, however, as appearing to be founded on correct principles, and as tending to suggest desirable courses for experimental researches. The overhanging part of the curve from *c* to *f* seems to represent a state in which there would be some kind of unstable equilibrium; and so, although the curve there appears to have some important theoretical significance, yet the states represented by its various points would be unattainable throughout any ordinary mass of the fluid. It seems to represent conditions of co-existent temperature, pressure, and volume, in which, if all parts of a mass of fluid were placed, it would be in equilibrium, but out of which it would be led to rush, partly into the rarer state of gas, and partly into the denser state of liquid, by the slightest inequality of temperature or of density in any part relatively to other parts. I might proceed to state, in support of these views, several considerations founded on the ordinary statistical theory of capillary or superficial phenomena of liquids, which is dependent on the supposition of an attraction acting very intensely for very small distances, and causing intense pressure in liquids over and above the pressure applied by the containing vessel and measurable by any pressure-gauge. That statistical theory has fitted remarkably well to many observed phenomena, and has sometimes even led to the forecasting of new results in advance of experiment. Hence, although dynamic or kinetic theories of the constitution and pressure of fluids now seem likely to supersede any statistical theory, yet phenomena may still be discussed according to the principles of statistical theory; and there may be considerable likelihood that conditions explained or rendered probable under the statistical theory would have some corresponding explanation or confirmation under any true theory by which the statistical might come to be superseded. With a view to brevity, however, and to the avoidance of putting forward speculations perhaps partly rash, though, I think, not devoid of real significance, I shall not at present enter on details of these considerations, but shall leave them with merely the slight suggestion now offered, and with the suggestion mentioned in an earlier part of the present paper, of the question whether in an extremely thin lamina of gradual transition from a liquid to its own gas, at their visible face of demarcation, conditions may not exist in a stable state having a correspondence with the unstable conditions here theoretically conceived.

ALTERNATION OF GENERATIONS IN FUNGI

IT has long since been shown that certain fungi pass through an alternation of generations on the same plant. The Rev. M. J. Berkeley demonstrated that in the case of the common "bunt" at least four consecutive forms of reproductive cellules were produced. In the majority of Uredines there are two forms of fruit, but these can scarcely be regarded as an alternation of generations, since there is no evidence that the spores of *Trichobasis* by germination, or otherwise, produce the bilocular spores of *Puccinia*. In *Podisoma* and *Gymnosporangium* (if the two genera are really distinct) the bilocular spores germinate freely and produce unilocular secondary spores. Prof.

me in the Proceedings of the Royal Society for November 24, 1859, and in a paper submitted to the British Association in the same year. In the present paper, at the place to which this note is annexed, I adduce the like further supposition that a difficulty of making a beginning of change of state from gaseous to liquid may also probably exist.

Oersted contends that if these secondary unilocular spores are sown upon young plants of the *Sorbus aucuparia*, they will germinate, and that the ends of the germinating filaments penetrating the tissues of the leaf of the sorb will in turn produce the spermatogonia and peridia of *Rastellia cornuta*. This is very similar to the deductions of Prof. de Bary that the spores of the *Æcidium* which flourishes on the berberry may be employed to inoculate young plants of wheat, and will produce as a result the wheat-mildew (*Puccinia graminis*), which he contends is another generation of the berberry fungus completed upon a different host. (See NATURE, vol. ii. p. 318.)

Such experiments as those of Professors Oersted and De Bary must always prove unsatisfactory unless performed with extraordinary care, and until confirmed by other observers. One or two strong presumptions can always be urged against them, and require to be boldly faced. Wheat is very subject to the attacks of mildew (*Puccinia*), and the results claimed for certain experiments are that they have produced by inoculation with other spores the common *Puccinia* upon wheat plants, to which the wheat is particularly addicted all the world over. Admitting that the *Æcidium* spores sown on the leaves of young wheat plants germinate, and that the germinating filaments enter the tissues of the leaf, are we therefore justified in affirming, or admitting that the inoculating spores produce the *Puccinia* which ultimately exhibits itself? Is it not more feasible to believe that the germination of the foreign spores have only served to stimulate the latent germs of the *Puccinia* already present in the tissues of the wheat plant? What guarantee is afforded by those who have already experimented, that the wheat plants experimented upon would not ultimately, without inoculation, have developed precisely the same parasite as that supposed to have been produced by inoculation? Assuming also that the experiment was pursued in the opposite direction, and that the spores of the wheat mildew were sown upon young plants of the berberry, if the *Æcidium* should soon afterwards appear on the leaves, it is easy enough to jump to the conclusion that they were produced by inoculation, but assumption is insufficient since the berberry is very subject, year after year, to bear on some of its leaves the peridia of the *Æcidium*. What evidence could be given that the *Æcidium* would never have appeared but for the inoculation? It is manifest that no amount of care in cultivation under bell glasses or other exclusion from foreign influences is sufficient against a contingency which dates back to the seed of the nurse-plant.

If the sowing of the spores of *Æcidium* upon the leaves of wheat resulted in the production of an *Æcidium* identical with it, or if the inoculation of berberry with wheat mildew was succeeded by the development of a *Puccinia* of a very similar character, it would not be so difficult to believe in both cases that the resulting forms might have been caused by inoculation. When the fungi assumed to be produced by inoculation are those to which the nurse-plants are particularly and specially subject, the evidence should be very strong before it is affirmed that a very natural phenomenon had an unnatural* cause.

The evolution of *Rastellia* on the leaves of the "mountain ash" by inoculation with *Podisma* spores is quite analogous to the berberry and wheat fungi. It is common enough to find the *Podisma* on junipers, and the *Rastellia* on "mountain ash," and the presumption would be, if young plants of "mountain ash" were covered up ever so carefully with bell glasses, notwithstanding that the leaves had been sprinkled with the spores of a dozen other species of fungi, if *Rastellia* made its appearance, that it bore no relation whatever to any of the foreign spores which had been sown upon it, but would have been there

independent of inoculation, or bell glasses, or a dozen like contingencies.

In both cases to which allusion has been made above, there is need of the strongest evidence to show that the ultimate parasite would not have made its appearance but for the inoculation, or that the whole chain was completed which connected the inoculating spore with the parasite produced. It would be folly to contend against facts for the sake of theory, and absurd to combat conclusions fairly deduced from ascertained facts; but in this instance we are bound to contend, in honesty to our convictions, that in neither case has Oersted or De Bary shown to our satisfaction that they were justified in declaring for an alternation of generations of fungi in which the stages were passed on different nurse-plants. When the facts are confirmed and established will be time enough to inquire whether both stages are essential the one to the other, and, if so, how it is that mildew wheat in such great profusion can be found in districts where berberry bushes are unknown, or why the *Rastellia* on the leaves of pear trees should be so common in counties where scarcely a savin can be found.

I have been led to these observations partly because some writers have accepted the conclusions at once as if they were incontrovertible facts, and partly because I have personally been charged with ignoring (by silence, it is presumed) the results of De Bary and Oersted's experiments, whereas I only claim the privilege of doubting, where I would not dare to deny.

M. C. COOKE

THE SCIENCE AND ART DEPARTMENT

THE following important Minute on the subject of Science instruction has recently been issued by the Committee of the Privy Council on Education:—

It appears desirable that the instruction of students in Science, after they have completed the course of the ordinary elementary school, should be carried on more methodically than is at present the case, and that they should not attempt to grapple with the more advanced forms of Science until they have received sound and practical instruction in those subjects which constitute the groundwork of all the physical sciences.

To this end the course of instruction specified below has been prepared as adapted both to secondary day schools and to night classes.

It will depend on circumstances, especially if the student can only attend night classes, how many subjects he can take up in one year. It must therefore be understood that the course should not only comprise the subjects named below, but also that they should be taken in the order in which they are stated.

The terminology used is that of the Science and Art Directories. The syllabus of subjects there given states precisely what is included under each head. And it is assumed that before commencing the following course, the student will have been made acquainted, in the elementary school, with the elements of arithmetic, and the primary conceptions of physical science.

COURSE OF INSTRUCTION.—*First Year*.—Mathematics (Subject V., First Stage); Freehand Drawing (2nd Grade Art); Practical Plane Geometry (2nd Grade Art); Elementary Mechanics, including the physical properties of liquids and gases (Subject VI., First Stage); Physics: Acoustics, Light and Heat (Subject VIII., First Stage). *Second Year*.—Chemistry, Inorganic (Subject X., First Stage), with practical work; Physics: Magnetism and Electricity, frictional and voltaic (Subject IX., First Stage); Mathematics (Second Stage and, if possible, Fourth Stage, Subject V.); Practical Geometry, Plane and Solid (Subject I., First Stage); Animal Physiology, if possible (Subject XIV., First Stage). The student

* The term "unnatural" is employed here in the sense that the presumed cause is one of which we have no experience, and which is contrary to the ordinary course of nature.

should also, during the first and second year, work at mechanical drawing as provided for in the Art Directory, Stage 23a. *Third Year.*—The work of this year must depend so much on the student's aptitude, and the progress he has made in the preceding course, that it is impossible to lay down the subjects for the third year's course with any definiteness. It is essential that before continuing his course, or commencing new subjects, he should have a sound knowledge of the first stage of Mathematics, Elementary Mechanics, Physics, and Chemistry; that he should have such a knowledge of practical Geometry and Mechanical Drawing as to be able to draw and read simple plans, elevations, and sections with readiness, and that he should have sufficient facility in Freehand Drawing to make clear and neat explanatory diagrams.

When these subjects have been mastered, the student should, while continuing his studies in mathematics, take up the first stage of Animal Physiology, if he has not already done so. He will then be in a position to specialise his studies with advantage in one of the following groups, according to his requirements, taking up, for instance—1. Physics and Chemistry and Metallurgy; 2. Theoretical and Applied Mechanics, Steam, and Machine Construction and Drawing; 3. Theoretical and Applied Mechanics, and Building Construction and Drawing; 4. Biology; 5. Geology, Physical Geography, Mineralogy, and Mining. The student may also with advantage continue his freehand drawing and practical geometry.

The foregoing course is framed to lay the foundation of a thorough and systematic scientific training. It must, however, be understood that this course, though strongly recommended for all those who can devote sufficient time to go through it, in no way supersedes or does away with the power of holding special classes in different subjects for those who have not these opportunities, or diminishes the aid at present offered to such classes.

The fact of the course being intended as a systematic training will also explain the omission of certain subjects which are not to be considered unimportant because they find no place in the course. Thus systematic Botany will be found of very great use as a preliminary to the study of natural science. As such it may be taught in elementary schools before this course is commenced. But, further than that, it cannot be considered a step in a systematic course till the student takes it up as a portion of Biology in his third year. In the same way Physical Geography is a subject which may with great advantage be studied in all schools, and is especially adapted for students who cannot go through a systematic course. The first elements of Physical Geography, treating broadly the outlines of physical science and describing its objects, should, as stated above, be taught as an introduction to its systematic study. But Physical Geography in its general sense covers so wide a field, embracing to a greater or less degree so many branches of Science, that it does not fall into a systematic course of training in science, though as a means of imparting highly valuable general information, as distinct from a systematic training, it may be strongly recommended.

ARCTIC EXPLORATIONS

AN excellent paper on the above subject appears in NATURE of Nov. 30, and it is to be hoped that it may have the desired effect of reanimating in our Government and among scientific men a fresh interest in the prosecution of a further survey of the unknown seas round the Pole.

Agreeing as I do with the writer as to the great importance of such an exploration as he recommends, I cannot so readily acknowledge the correctness of his opinion as to the advantages of the route by Smith Sound over that along the west shore and to the north of Spitzbergen,

from which point Parry (the greatest and noblest of arctic explorers) attempted to reach the Pole with boat sledges in 1827.

Parry had, I think, on this occasion chosen the right route, but the wrong season of the year; for he attempted the journey in the month of July, instead of in March, April, May, and June.

At Spitzbergen a vessel can always get as far as 80° north, probably higher; for Mr. Lamont has, during the last two summers, on his pleasure cruises, readily reached the latitude named.

I had it from the great navigator Parry himself, that the ice he saw to the north of Spitzbergen would not have been difficult to travel over at the proper season of the year.

The farthest north point reached with much difficulty by ships in Smith Sound has been 78°40', and we have not the least warrant or certainty that any future expedition may be able to winter its ship or ships nearer the Pole by this route.

From lat. 78°40' the distance to the Pole is 680 geographical miles, making the journey there and back 1,360 miles in a straight line.

But surely no experienced Arctic traveller would be sanguine enough to believe that he could take a "bee line" in a sledge journey to the Pole; in fact, he would require to make an allowance of about one-fifth for obstructions by rough ice, probable contour of coast line, &c., so that the actual distance to be made would be $1,360 + 270 = 1,630$ geographical miles, a journey 200 or 300 miles longer than any that has yet been accomplished, even by that admirable Arctic traveller, the late Lieut. Meham. Yet Meham, in his two longest journeys of 1,200 or 1,300 miles each (I forget whether these are geographical or statute miles, but I think they are the latter), had advantages not likely to be found in a journey to the Pole. On the one occasion deer, musk-cattle, and other game were so abundant and so tame that he could and did easily kill as many as the party required, and could have killed many more. On the other occasion he was travelling along a known route, at several points of which depots of provisions had been placed by ships wintering there, or by other means, from which he was enabled to obtain supplies both on the outward and homeward march.

Mr. Markham says that a ship can always get so far north in Smith Sound that the Pole can be reached by a journey from it with sledges of 968 miles there and back.

By what powers of reasoning or rule of arithmetic this conclusion has been arrived at I am at a loss to know, unless there is always a certainty of ships getting into winter quarters in Smith Sound as far up as 82° latitude, yet Kane was stopped 200 miles south of this, and Hayes even at a greater distance.

The Spitzbergen route has never had a fair trial with sledges over ice either with or without the aid of dogs, and I believe that if the Pole is ever to be reached, it will be by it, and not by Smith Sound. The distance to be travelled will not probably be less than 1,400 geographical miles, possibly more, a journey practicable enough under favourable circumstances, but by no means easy of accomplishment.

JOHN RAE

NOTES

At the Anniversary Meeting of the Fellows of the Royal Society on Thursday last, Lieut.-General Sir Edward Sabine, R.A., K.C.B., resigned the office of president, which he has filled since 1861, and the Astronomer Royal was elected to fill the presidential chair. The following gentlemen were appointed officers and council for the ensuing year:—President: George Biddell Airy, M.A., D.C.L., LL.D., Astronomer Royal. Treasurer: William Spottiswoode, M.A. Secretaries: William Sharpey, M.D.,

LL.D.; Prof. George Gabriel Stokes, M.A., D.C.L., LL.D. Foreign Secretary: Prof. William Miller, M.A., LL.D. Other Members of the Council: George J. Allman, M.D.; John Ball, M.A.; George Burrowes, M.D.; George Bask, P.R.C.S.; Prof. Robert B. Clifton, M.A.; H. Debus, Ph.D.; Prof. P. M. Duncan, M.B.; Prof. G. Carey Foster, B.A.; Francis Galton; Thos. A. Hirst, Ph.D.; Sir John Lubbock, Bart.; Sir James Paget, Bart., D.C.L.; The Earl of Rosse, D.C.L.; General Sir E. Sabine, R.A., K.C.B.; Isaac Todhunter, M.A.; Sir Charles Wheatstone, D.C.L. The President's annual address was occupied by a *résumé* of the most important advances in science, mainly physical, during the year. After alluding to the loss sustained by the Society in the deaths of Sir John Herschel, Mr. Babbage, and Sir R. Murchison, General Sabine referred particularly to the munificence of Mr. J. P. Gassiot, by which the Kew Observatory has been transferred to the Royal Society in trust, with an income of 500*l.* per annum towards the cost of carrying on and continuing magnetical and meteorological observations with self-recording instruments, and any other physical investigations that may from time to time be found practicable and desirable in the present building at Kew belonging to the Government; or, in the event of the Government at any time declining to continue to place that building at the disposal of the Royal Society, then in any other suitable building which the Council of the Royal Society may determine. The following papers and investigations were also specially named by the president:—"On the Dependence of the Earth's Magnetism on the Rotation of the Sun," by Prof. Hornstein, of Prague; the Pendulum Experiments in India, by the late Captain Basevi, R.N.; Mr. Ellery's report on the Great Melbourne Telescope; the Investigations of the Lunar Atmospheric Tide, by M. Bergsma, of Batavia; and the Memoir by Prof. Heer, of Zurich, on the Fossil Plants brought from Greenland by Prof. Nordenskiöld. The Copley and Royal medals were then awarded, as already noted.

WITH regard to the Australian arrangements for observing the Total Eclipse of Tuesday next, we learn that the Royal Society of Victoria (not of New South Wales, as had been previously reported) were up to the end of September making vigorous preparations for an Expedition, but that at that time they were afraid that their plans would be seriously frustrated by the failure of Government aid, which they had been led to expect would be liberally granted. Mr. Ellery, the president, and Mr. Rusden, the secretary of the Royal Society of Victoria, were exerting themselves to the utmost to secure the success of the Expedition, which was to start not later than November 22nd. By the most recent Melbourne papers of October 9 and 10, we learn that, notwithstanding the supineness displayed in the matter by the other Australian colonies, it was still hoped that the Government of Victoria would render such pecuniary assistance as would make it possible for the Expedition to set out with some chance of success in obtaining results of scientific value. The number of persons who had already agreed to join the expedition up to that date was twenty, of whom four or five were of Adelaide, three of Sydney, and one or two of Tasmania. No very certain information had been procured about the prevailing weather in the latitude where the eclipse will be visible. The destination of the steamer will be Cape Sidmouth, about midway between Cardwell and Cape York, where there is some risk of the weather being unfavourable, inasmuch as during December the N.W. winds frequently bring heavy rain. Probably the Expedition will be broken up into several observing parties, and two or more stationed at different points of the mainland, and one on a neighbouring island.

THE elevation of Mr. W. R. Grove, Q.C., to the judicial bench is a noteworthy event in the history of the *personnel* of Science. It is well known that the author of the "Correlation of

Forces," and *quondam* President of the British Association, is an authority of no mean rank on some of the most abstruse questions of law.

THE Exhibition of Stone Implements (Neolithic and Savage) at the Apartments of the Society of Antiquaries in Somerset House will be open at the meeting of the Society this evening, and from the 8th to the 14th inclusive from eleven to four. Cards of admission may be obtained from the secretary.

We learn from Prof. H. A. Newton, of New Haven, Conn., that between 11²⁰ P.M. on November 13, and 1⁴⁵ A.M. November 14, ninety-eight meteors were seen, though the sky was cloudy. Not more than one-tenth of them were, however, regarded as belonging to the meteor stream of November. Prof. Newton thinks that if the earth met the stream this year, it was either before or after the interval of observation.

AN application has been received by the Kew Committee of the Royal Society from Dr. Jelinek, Director of the "Central Anstalt für Meteorologie und Erdmagnetismus," to procure for that establishment a set of self-recording magnetographs similar to those at Kew. The request has been complied with; and it is hoped that the apparatus will be ready for transmission to Vienna in March next, being the time named by Dr. Jelinek as that at which the new building in course of erection in that city is expected to be completed. The Committee has also been apprised by a letter from Mr. Stone, Astronomer Royal at the Cape of Good Hope, that he had at that date applied to the Admiralty for a set of magnetographs, similar to those at Kew, to be employed at the Cape. The Kew Committee hold themselves in readiness to supply the desired apparatus when they may receive directions to that effect from the Admiralty; such directions, however, have not yet been received. If Mr. Stone's request is granted, the Cape Observatory will be the third in the British Colonial Dominions employing such instruments, the other two being the Colaba Observatory under Mr. Chambers at Bombay, and the Mauritius Observatory under Mr. Meldrum.

It is reported that the French Government intends to establish two schools, one at Lyons and the other at Nancy, in place of the Strasburg medical school. The Strasburg professors are to go to Lyons; and it is expected that that school will assume an important position in consequence of the large amount of hospital accommodation in the city. At Nancy, physics, chemistry and physiology will be more especially taught.

Harper's Weekly announces the death, in Boston, of the Rev. J. A. Swan, on October 31, at the age of forty-eight. Mr. Swan has been long known among his New England friends for his love of natural history and his skill in the use of the microscope; and during his residence at Kennebunk, although a devoted pastor in that village, he found time to make numerous important explorations and observations in the natural history of the vicinity. Failing in health a few years ago, he visited Europe, and on his return was appointed to the responsible post of secretary of the Boston Society of Natural History, in connection with Prof. A. Hyatt, succeeding Mr. Scudder in charge of the business of the society. Apart from his scientific accomplishments, Mr. Swan was endeared to all his friends by personal qualifications of the rarest merit.

THE Society of the Friends of Science, in Posen, propose, on February 19, 1873, to celebrate the 400th birthday of the eminent astronomer, Nicholas Copernicus, at his birth-place, in the village of Thorn. In addition to the festivities of the occasion, they intend to publish an accurate biography of their countryman, and to prepare a monumental album, as also to strike an appropriate medal. A prize of 500 thalers is offered for the best biography that can be prepared before January 1, 1872, to be based only upon authentic documents.

WE have received the first number of "The German Quarterly Magazine; a Series of Popular Essays on Science, History, and Art." The plan of the publication is to give in English such essays, selected from the "Sammlung gemeinverständlicher wissenschaftlicher Vorträge," edited by Profs. Virchow and Franz von Holtzendorff, as are likely to interest the English reading public, and also original contributions; the numbers presenting alternately selections from the departments of Science, History, and Art. The present number contains three papers:—"The Cranial Affinities of Man and the Ape," by K. Virchow; "Sight and the Visual Organs," by A. von Graefe; and "The Circulation of the Waters on the Surface of the Earth," by H. W. Dove; all papers of great interest and importance, but losing something to the English reader from the German phraseology in which the translations are clothed. They are illustrated by good woodcuts, and the subscription to the magazine is 10s. per annum.

MESSRS. LONGMAN & Co. are about to publish a volume by Mr. Serjeant Cox, entitled "Spiritualism answered by Science," in which he will detail the arguments that satisfied himself and the other scientific investigators that the phenomena of alleged "Spiritualism" are purely physical, and in no manner associated with spirits of the dead.

DR. BESSELS, the director of the scientific corps of Captain Hall's steamer *Polaris*, in a letter addressed to the president of the American National Academy of Sciences, dated Godavén, August 16, states that he had already made some important observations in regard to the physics of the northern seas, such as a peculiar coloration of the water and an unexpectedly high specific gravity, the maximum density noticed being 1.025. His experiences with his colleagues, Mr. Bryan, the astronomer, and Mr. Meyer, the meteorologist, have been very satisfactory; the former gentleman having made a number of successful azimuth observations, and the latter approving himself an excellent mathematician and an accomplished observer, and an honour to the Signal Service, from which he was detailed for duty with Captain Hall.

THE recently published report of Commissioner R. W. Raymond upon statistics of mines and mining in the states and territories west of the Rocky Mountains for the year 1870, forms a stout volume of nearly 600 pages, illustrated by a number of plates and sections, embodying the result of a laborious personal examination, and that of several assistants. The report contains a detailed account of the present condition of the mining industry in California, Nevada, Oregon, Idaho, Montana, Utah, Arizona, New Mexico, Colorado, and Wyoming, together with interesting statements in regard to improved metallurgical processes, such as especially relate to the treatment of auriferous ores, the chlorination and smelting of silver ores, &c. There are also chapters on narrow-gauge railways and their adaptation to mining regions, the mining law, the geographical distribution of mining districts, the origin of gold ingots and gold-dust, and the bullion product. The Commissioner congratulates the country upon an increased prosperity in the mining industry, as seen not only in an augmented bullion product, but an improved tone in the business itself, and relief from more or less of the irritating and burdensome questions that have hitherto been connected with the mining interest. Although the excitements which so frequently carry off the miners and settlers of one region into a new locality have been comparatively rare, yet there have been a few of special note. Among those mentioned by Mr. Raymond are those caused by the discovery of gold in Southern California, near San Diego; the discovery of silver in the Barro Mountains, and the rumours of rich placers on Peace River, far into the interior of British Columbia; the bars of Snake River; several localities in Nevada, and others in Utah; the silver mines in the Caribou district of Colorado, &c.

COLDING ON THE LAWS OF CURRENTS IN ORDINARY CONDUITS AND IN THE SEA

III.

LET us now direct our attention to the polar currents, and especially to that one which from Spitzbergen proceeds to the south-west along the coast of Greenland as far as Cape Farewell. It will be seen that this current has received an impulse from the force of rotation, and rises about one foot towards the west coast of Greenland, an effect which however ceases as soon as it has passed the southern point of that country. As soon as the resistance which compelled the current to follow the line of the coast in proceeding to the south-west disappears, it can no longer continue in the same course, but takes a westerly direction towards Labrador, partly in consequence of the rotation of the earth, partly because the level of the current is then higher than that of the waters of Davis Strait. After having advanced a little into the strait, the polar current encounters the currents coming from the north by Baffin's Bay, and joins them in their progress to the south-east along the coast of Labrador, towards which it slopes in virtue of the rotation of the earth. During this passage, and until its arrival in the neighbourhood of Newfoundland, this current is stemmed by the force of rotation, and ought, consequently, to present a slope all along Davis Strait and the east coast of Newfoundland as far as the Gulf Stream. During its course southwards along this course, the polar current is elevated towards the land by the earth's rotation; but as soon as it has passed Cape Race, this resistance suddenly disappears, and the same phenomenon is reproduced as at Cape Farewell. The current bends suddenly to the south-west, and follows the coast as far as Florida, while its breadth and the volume of its water continue to diminish.

From Newfoundland to Florida, a distance of about 500 miles, the Gulf Stream and the polar current flow constantly side by side, under the impulse of the earth's rotation, which raises the polar current towards the land and compels it to follow all the ins and outs of the coast. But what force is it that impels the Gulf Stream, which flows freely in the ocean, to keep by the side of the polar current in all its windings, instead of taking the more easterly direction, which the rotation of the earth tends to give it? It is, of course, gravity, to wit, the force resulting from the slope which the Gulf Stream presents from right to left perpendicular to its direction throughout its entire breadth, a slope which is 12 feet from the point where the current debouches into the Atlantic to New York, and about one foot from New York to the place where, after having approached the shores of Europe, it separates into two branches. And if it be asked why the Gulf Stream has this slope; the reason evidently is that the water of the polar current has a specific gravity greater than the water of the Atlantic, and ought consequently to have a lower level than that of the latter sea, since the water beneath is in equilibrium. That this is the real state of the matter is fully confirmed by the researches made in recent years in the Gulf Stream at the instigation of the American Government, and which leave no room to doubt that this current has not kept its place on account of the difference of density which exists between the waters of the polar current and those of the Atlantic. Under these circumstances it is easy to see that the Gulf Stream ought to follow all the sinuosities of the polar current as far as Newfoundland.

But while the Gulf Stream ought thus to be considered as presenting a uniform slope from the Atlantic towards the polar current, the researches undertaken by the American Government prove that the bottom of the Gulf Stream could be in equilibrium only if that current had an inclination directed away from the polar current towards the Atlantic, such that its maximum level would be nearly one-third of the distance from the polar current. Under the actual conditions, then, there is no equilibrium. The waters of the polar current exercise upon the Gulf Stream a pressure which increases with the depth, and causes a continual afflux of cold water, especially in its lower depth. In proportion as these cold waters penetrate into the Gulf Stream, it communicates to them its heat and its motion, and in proportion as it is raised under the influence of the pressure of the polar current driving away the water which it displaces, its breadth ought to go on increasing. But in order that the breadth of the Gulf Stream may increase, it is necessary that its level in the centre of the current be elevated above that which corresponds to the equilibrium of the surface, so that the force of

rotation should acquire the preponderance necessary to produce an enlargement of breadth towards the east; and this elevation of the level gives birth at the same time—from the middle of the Gulf Stream to the polar current—to the surface current of warm water which has been ascertained to exist by the American Commission.

It follows then from what precedes, that on the one hand the polar current penetrates at all points into the Gulf Stream, nearly as far as its surface, which sends to the polar current a surface-current of warm water from twenty to fifty fathoms deep; and, on the other hand, that the Gulf Stream ought, throughout the whole of its depth, to exercise upon the waters of the Atlantic a pressure which forces them to give place to those which it receives from the polar current, and which it draws along with it.

The researches which have recently been made as to the Gulf Stream all appear to confirm these conclusions, so that if we suppose that the volume of the Gulf Stream is increased by all the water which the polar current loses in its course, it will follow that if we designate by Q the volume of the Gulf Stream at Bemini, and by q that of the polar current in any section between Newfoundland and Florida, the volume of the Gulf Stream, for the same section, will be equal to $Q + q$. After that, it is necessary that the polar current—which, from the east coast of Newfoundland, flows towards the Gulf Stream, and from Cape Race takes a south-westerly direction along the American coast—gives up in its passage towards Florida all its water to the Gulf Stream. If, then, we assume the speed of the polar current to the south of Newfoundland to be 1·8 feet per second, its breadth 50 miles, and its depth 900 feet, it will be found that its delivery per second is 1,600,000,000 cubic feet, which makes that of the Gulf Stream to the south of Newfoundland 3,200,000,000 cubic feet per second.

From the southern part of the North Atlantic, then, between the equator and 30° of latitude, it discharges at the rate of 1,600,000,000 cubic feet per second; but besides the loss which has been accounted for, there is another which is due to evaporation; the latter deprives the Gulf Stream of a quantity of water greater than that which falls into it in the form of rain, and which flows into it from the neighbouring lands. To calculate this difference, we can make use of the results of the researches which were made in 1860 at St. Helena by Lieut. Haughton. We thus find that the excess of evaporation in the Atlantic, between 0° and 30° of latitude, is equivalent to a mean height of water of 0·22", which, after deducting one-tenth for the water which comes from rivers, gives a loss of 50,000,000 cubic feet per second. The total quantity of water, then, which passes from the Atlantic between 0° and 30° of N. latitude, can be stated as equal to 1,650,000,000 cubic feet per second.

If we then admit that two-thirds of all the surface of the lands situated to the north of the 30th degree of latitude send directly or indirectly their waters to the Atlantic, and if we estimate the quantity of rain which annually falls upon that surface, the north part of the Atlantic will receive per second an addition of 50,000,000 cubic feet of water, or, about the same quantity which is carried off by evaporation from the south part between 0° and 30° of N. latitude.

But it follows hence that since the southern branch of the Gulf Stream is formed by the water which flows from the south part of the North Atlantic, it ought to have a delivery of 1,650,000,000 cubic feet per second; and, as the delivery of the entire current, after having passed Newfoundland, may be stated at 3,250,000,000 cubic feet, it follows that that of the northern branch is 1,600,000,000 cubic feet, while the united polar currents ought to represent a volume of 1,650,000,000 cubic feet per second. At St. Augustine the depth of the Gulf Stream is about 300 fathoms, which goes on diminishing regularly, as far as Newfoundland, where it is 1,000 feet. From Newfoundland, where it has a breadth of eighty miles and a speed of two feet, the current proceeds E.N.E., with a decreasing speed and an increasing breadth; at the end of 300 miles it has a depth of 200 and odd fathoms, a speed of 0·6 feet, and a breadth of 200 miles. Moreover, during this part of its course it rises about 2 feet above its level at Newfoundland. Until it attains this height, the Gulf Stream forms only a single current maintained by the fall of 1 foot, which it presents from right to left; but as soon as it reaches that, its southern part presents a slope sufficient to give birth to a branch which proceeds to the south-east, towards the African coast, at a speed of 0·6 feet, and with a delivery of 1,650,000,000 cubic feet per second. When the latter current reaches the 30th degree of N. latitude,

it meets the north-east trade-wind, which urges it towards the south.

But while the southern half of the Gulf Stream proceeds towards the south, its northern half, whose delivery per second is 1,600,000,000 cubic feet, pursues its course towards the north, along the shores of Great Britain, as far as the 60th degree of latitude in this passage, during which the current rises towards the land and gradually increases in breadth from 100 to 150 miles, while its speed diminishes from 0·6 to 0·3 of a foot per second, it is subjected to the impulse of the earth's rotation, and its western margin, which naturally blends with the surface of the Atlantic, is raised from 11 feet through a course of 140 miles, so that at the 60th degree of latitude this side is $3\frac{1}{2}$ feet above the level of the ocean at Newfoundland.

After the Gulf Stream, which throughout this course has a depth of from 200 to 300 fathoms, reaches the north coast of Scotland, about two-thirds of its waters proceed eastwards towards the Norwegian coast, while the other third runs against Iceland, and afterwards continues its course to the north-west to the polar current of Greenland. The latter branch, which the force of rotation raises towards the land, has a depth of 200 and odd fathoms, and a breadth of about 50 miles; in order to be able to advance towards the polar current with a speed of about 0·3 feet per second, a fall of nearly half a foot is necessary. If next we remark that the northern Gulf Stream, towards the north point of Scotland, presents an elevation of 1·5 feet towards the land, we shall easily see that the branch of the Gulf Stream, which proceeds to the north-west, has, along the Icelandic coast, a level which exceeds by half a foot the southern margin of the same current. From this it follows that the waters which skirt the coast of Iceland encounter the polar current on the west of that island at a level higher by $3\frac{1}{2}$ feet than the surface of the Atlantic at Newfoundland. But while these waters advance towards the polar current in virtue of the above-mentioned fall, those of the southern margin of the Gulf Stream have precisely the same level as the polar current. The waters of the western side of the north branch of the Gulf Stream, which are forced to bend towards the west after having reached the 60th degree of north latitude, cannot then continue their course towards the polar current; they spread themselves over the surface of the Atlantic and take a southerly course towards Newfoundland, on account of the difference of level. With regard to those parts of the current situated between the north and south boundaries of this branch of the Gulf Stream, they are, according to their position, drawn for a shorter or longer time still towards the polar current, before taking their course towards the south; and it is thus evident that the warm current must spread itself over the whole surface of the Atlantic between the Northern branch of the Gulf Stream and the polar current which descends from Greenland.

If next we turn our attention to the progress of the polar current from the east coast of Greenland, starting from the following data, viz., that the eastern margin of this current, about 65° north latitude, on the west of Iceland, has a level of $3\frac{1}{2}$ feet higher than that of the Atlantic at Newfoundland, and that it pursues a course to the south-west at the rate of $\frac{2}{3}$ of a foot per second—we see clearly that it is obedient to the impulse communicated by the rotation of the earth. Moreover, let us estimate, after Irminger, the breadth of the current at 40 miles, and suppose that the half of the water which the Gulf Stream carries into the icy sea, as well as the half of that which falls in the form of rain or snow, returns towards the south with the current, while the other half descends by Baffin's Bay; we then find that the force of rotation raises the polar current, whose depth may be estimated at 1,000 feet, one foot above its eastern margin, and, regarding the speed as constant as far as the south point of Greenland, we arrive at the result that, along its eastern side, which naturally blends with the Atlantic, its surface must continue to rise as far as Cape Farewell, from $3\frac{1}{2}$ to 5 feet above the level of the ocean at Newfoundland. If, after having doubled Cape Farewell, the Gulf Stream descended straight towards Newfoundland, the water in Davis Strait ought to rise to a height sufficient to hinder the current from moving in a more westerly direction. But, as the water in Davis Strait cannot have a higher level than is necessary to impel towards the south the tributary bodies of water as rapidly as they join it, and, as for this purpose, at the 63rd degree of north latitude, an inclination of only $3\frac{1}{2}$ feet above the level of the sea at Newfoundland is required, the polar current, on arriving at Cape Farewell, presents towards Davis Strait a slope of $2\frac{1}{2}$ feet along

the Greenland coast, and a foot and a half along its opposite margin, and in consequence of this slope proceeds several degrees into the Strait. But as Baffin's Bay and Davis Strait, as has been said before, are traversed by a polar current descending towards the south-east, it ought to have an inclination in that direction; and it is on this account that the current from the east coast of Greenland, after advancing for some time into Davis Strait, is forced to run westwards towards the coast of Labrador, along which it then flows southwards after joining the current from Baffin's Bay. The two united polar currents, whose delivery may be estimated at 1,200,000,000 cubic feet per second, have a breadth of fifty miles, a speed of $\frac{1}{2}$ of a foot per second, and a depth of about 250 fathoms. They flow to the south-east, under the influence of the earth's rotation, which raises them towards the coasts of Labrador and Newfoundland, and continue their course along the latter towards the Gulf Stream until they have doubled Cape Race, when they bend westward and make for Florida.

If now we return to the warm current which, from the Gulf Stream, curves round the south of Iceland, and then spreads itself gradually over the cold waters of the Atlantic, we see that on its arrival at the south point of Greenland, it rises from left to right, from the Gulf Stream to Cape Farewell, about 2½ feet, which shows clearly that its course is really to the south. Moreover, this elevation from left to right enables us to give a more satisfactory account of the conditions of currents. In short, the western margin of the warm current accompanying the polar current, ought, along the latter, to have a depth of 1,000 feet and a speed of $\frac{1}{2}$ of a foot; and as the speed of the current diminishes regularly in approaching the Gulf Stream, and as all the parts of the current follow, as far as Cape Farewell, and as all the parts of the current follow, it follows that the speed along the Gulf Stream ought to be at the rate of about $\frac{1}{4}$ a foot per second. But if the returning branch of the Gulf Stream proceeds to the south-west with a fall of $\frac{1}{4}$ a foot on its west border, it follows that the depth of the current ought to be 76 feet. By determining in the same way the depth for a certain number of points of a transverse section, and by calculating according to these data the total delivery of the current, we find that it is raised to 410,000,000 cubic feet per second, which perfectly accords with the result which we ought to obtain. If next we inquire how the various parts of the warm surface current move under the united action of the slope and the earth's rotation, we ascertain that this current ought to follow the course of the polar current which gradually absorbs the waters that penetrate underneath, the water of the current being more dense than that of the polar current, and we find at the same time that in thus flowing towards the polar current the water ought to spread itself all over the Atlantic as far as Newfoundland.

After having thus shown that the preceding theory accounts in a tolerably complete manner for all the movements of the ocean currents, I shall add, in conclusion, that it is very possible, considering our imperfect knowledge of the progress of currents, that many details may be very different from those which have been expounded above; but, so far as the main question is concerned, I believe I am entitled to say with confidence that the laws of ocean currents are pretty much those which I have attempted to establish.

That these laws are equally applicable to the atmospheric currents is evident, and it is scarcely necessary to repeat, that in periods when the differences of temperature on the surface of the globe were greater than at present, all these currents were much stronger, and of a nature otherwise very energetic.

with the experiments, which are grouped under these three sections. (1) Experimental determination of the conditions which govern the development of microzymes in certain organic liquids to be used as tests. Having found in a number of cases that either contact with surfaces which had not been superheated, or the admixture of water which had not been boiled, was the exclusive cause of the growth of microzymes in the experimental liquid, it was inferred that water is the primary source from whence the germinal particles of bacteria are derived whenever they seem to originate spontaneously in organic solutions. A number of experiments were made with different varieties of water in ordinary use, in order to confirm the observations already made, and to ascertain if all waters possess the properties in question in a like degree. These experiments are detailed under the second section (2) Distribution of the Germinal Matter of Microzymes in ordinary Water. The results under this head were not deemed satisfactory. (3) Circumstances which determine the existence of microzymes in organic liquids and tissues, that is, whether the tissues and liquids of the living body participate in the zymotic property which exists in water and moist substances. The conclusion drawn from the facts is, that "it has appeared certain that there is no developmental connection between microzymes and torula cells, and that their apparent association is one of mere juxtaposition. Thus fungi are not developed, notwithstanding the presence of microzymes in the same liquid in which, microzymes being absent, but air having access, they appear with the greatest readiness." Finally, the writer is certain that, although air is the main source of what he calls fungus impregnation, as distinguished from impregnation with microzymes, yet the two acts may take place at the same moment, germs of torula being often contained in the same liquid media as the germ particles of microzymes.—"On the Colouring Matter of some Aphides," by H. C. Sorby, F.R.S.—"Observations and Experiments on the Red Blood Corpuscles, chiefly with regard to the Action of Gases and Vapours," by E. Ray Lankester.—"On Undulina, the type of a new group of Infusoria," by E. Ray Lankester.—"On the Circulation in the wings of *Blatta Orientalis* and other Insects, and on a new method of injecting the vessels of insects," by H. N. Moseley. After describing the method adopted for preparing and fixing the wings of insects for examination of the circulation, the writer proceeds to his experiences with the cockroach. The corpuscles in *Blatta* are so large that the circulation may readily be seen with a high power of a simple dissecting microscope. If an insect be carefully tied, the circulation may be observed in action for as long as twelve hours. Abundance of parasites were found in the blood vessels of *Blatta* and coleopterous insects. The method recommended for the injection of the circulatory system of insects is through the largest artery on the front border of the wing, and the injecting fluid is indigo carmine.—"On the production of Spores in the Radiolaria," by Prof. L. Cienkowski; translated from vol. vii., part 4, of the "Archiv. für Mikroskop. Anatomie." The observations on which this paper is based were mainly made upon Collophora and Collozoum. The capsule is the source of the zoospores. In the mature capsule the contents break up into a quantity of little spheroids.—"On the Peripheral Distribution of non-medullated Nerve-fibres," by E. Klein. The writer purposes treating of the nerves of the cornea, those of the nictitating membrane of the frog, of the canal in the tail of the rabbit, and of the mesentery. The present communication is confined to the nerves of the cornea, the remaining subjects are to be embodied in a second paper.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, Nov. 22.—The Rev. Thomas Wiltshire, M.A., in the chair. Mr. Samuel Baillie Coxon was elected a Fellow of the Society. The following communications were read.—I. "Notes on some Fossils from the Devonian Rocks of the Witzberg Flats, Cape Colony." By Prof. T. Rupert Jones, F.G.S. In this paper the author noticed some Devonian fossils like those of the Bokkeveld, found on Mr. Louw's farm on the Witzberg Flats, Tulbagh. *Orthoceras vitulatum*, Sandberger, was added to the South African list of fossils. The fossils under notice were stated by the author to help to substantiate the late Dr. Rubidge's view, that the old schists termed "Silurian" by Bain are of Devonian age, and continuous across the colony. Their presence in the Witzberg Flats was also

SCIENTIFIC SERIALS

THE Quarterly Journal of Microscopical Science for October, 1871. "The origin and distribution of Microzymes (Bacteria) in water, and the circumstances which determine their existence in the tissues and liquids of the living body," by Dr. Burdon Sanderson, F.R.S. This paper is occupied chiefly by details of experiments to determine the conditions which are fatal or favourable to the existence of microzymes in the liquid or gaseous fluids by which we are surrounded, in order to approach one degree nearer to an understanding of their influence on the processes which go on in the living body. After a definition of "microzymes," the author proceeds to their chemical composition and their relation to the media in which they grow. This portion is brief and incomplete. The remainder of the paper is occupied

shown to be conclusive against the idea of coal-measures being found there. Mr. Godwin-Austen remarked that the presumed Devonian species of South Africa appeared not to have been completely identified with those of European origin. Although, judging from the range of European marine mollusca, some of which were found of precisely the same species both in Europe and at the Cape, there was nothing surprising in the extension of any old deposit, yet it seemed unreasonable to suppose that the whole district over which the wide-spread Devonian rocks extend could have been submerged at the same time. He traced the original foundation of the Devonian system to the late Mr. Lonsdale, who, in the fossils found in the deposits of Devonshire, thought he traced sufficient grounds for a marked discrimination between those beds and those of Carboniferous age. Mr. Austen had, however, always regarded the Devonian system as merely an older member of the Carboniferous, holding much the same relation to it as the Neocomian to the Cretaceous; and he would be glad to see it recognised, not as an independent system, but merely as the introduction of that far more important system, the Carboniferous, during the deposit of which the globe was subject to the same physiological conditions. Mr. Etheridge did not agree with Mr. Austen as to the suppression of the name of Devonian system, and commented on its wide-spread distribution, and on the peculiar facies of its fossils, and their importance as a group. He was rather doubtful as to specific determinations arrived at from casts. Though the species of many fossils of Queensland procured by Mr. Daintree did not correspond with those of European areas, yet some of the corals were identical with those of South and North Devon, as were also the lithological characters of the containing beds. Mr. Seely objected to any attempt to supersede the arrangements of the South African rocks in accordance with the local phenomena, by correlating them too closely with any European series. The recognition of the correspondence in forms seemed to him more to prove a similarity of conditions of life than any absolute synchronism. As to the connection between the Devonian and Carboniferous systems, he agreed with Mr. Austen in regarding the one as merely constituting the natural base of the other. 2. "On the Geology of Fernando Noronha (S. lat. 3° 50', W. long. 32° 50')." By Alexander Rattray, M.D. (Edin.), Surgeon R.N. Communicated by Prof. Huxley, F.R.S. The author described the general geological structure of Fernando Noronha and the smaller islands which form a group with it. The surface-rock was described as a coarse conglomerate, composed of rounded basaltic boulders and pebbles, in a hard, dark red, clayey matrix. This overlies a hard, dark, fine-grained basalt, which forms the most striking of the bluffs, cliffs, and outlying rocks. The highest peaks in the group consist of a fine-grained, light grey granite. The author remarked upon the possible relation of the geology of these islands to that of the neighbouring continent of South America, and stated that there is evidence of the islands having been elevated to some extent at a comparatively recent period. 3. "Note on some Ichthyosaurian Remains from Kimmeridge Bay, Dorset." By Mr. J. W. Hulke, F.R.S. The author noticed some teeth found, with a portion of an Ichthyosaurian skull, in the Kimmeridge clay of Dorsetshire. The fragments of the snout were said to indicate that it was about three feet long and proportionally stout. The author indicated the character by which these teeth were distinguishable from those of various known species of *Ichthyosaurus*, and stated that they approached most closely to those of the Cretaceous *I. campylodon*. Mr. Seely did not consider that, in the main, the teeth of Reptilia afforded any criteria for specific determination. In the Cambridge Greensand, though there were five species of *Ichthyosaurus*, possibly including a second genus, the teeth found were so closely similar that it would have been impossible, from them only, to identify more than one species. Mr. Boyd Dawkins recognised in the specimens exhibited by Mr. Hulke a form of tooth he had found in the Kimmeridge beds of Shotover, near Oxford, but which he had been hitherto unable to attribute to any recognised species. He could not fully agree with Mr. Seely as to the absence of specific criteria in the teeth of Saurians, as, from his own experience, he was inclined to attribute some importance to their external sculpturing. 4. "Appendix to a 'Note on a New and Undescribed Wealden Vertebræ,' read 9th February, 1870, and published in the Quarterly Journal for August in that year." By Mr. J. W. Hulke, F.R.S. The author generically identified this vertebræ with *Ornithopsis*, Seely, *Streptospondylus*, Owen, and *Cetiosaurus*, Owen, taking the last to be typified by the large species in the Oxford Museum. He remarked that if this be the type of *Cetiosaurus*, *C. brevis*, Owen, can hardly belong to it, as

the trunk vertebræ are described as being of a totally different structure. Mr. Boyd Dawkins, who had recently visited Oxford, stated that he had there examined the remains referred to. There was, however, no tooth found with them of a character to show the nature of the food on which the animal subsisted. But one of his students had lately found in the same pit that had afforded the remains, a tooth corresponding in its principal characters with those of *Iguanodon*, with which, therefore, the *Cetiosaurus* seemed to be allied, so that it was probably a vegetable feeder. Mr. J. Parker had lately procured from the Kimmeridge clay a number of Saurian remains, and among them were some vertebræ of *Megalosaurus*, to which were articulated others presenting distinctly the characters of *Streptospondylus*. He thought that probably many of the supposed Streptospondylid vertebræ might prove to belong to the cervical region of Dinosaurians. Mr. Seely disputed the attribution to *Cetiosaurus* of the vertebræ described, and questioned whether the remains at Oxford might not be assigned to *Streptospondylus* or *Ornithopsis*. The depressions in the vertebræ, which might be connected with the extension of the air-cells of the lungs, did not exist in *Cetiosaurus*, but were to be found in *Megalosaurus*. As to the premaxillary tooth mentioned by Mr. Dawkins, he was uncertain whether it should be referred to what he considered as *Cetiosaurus* proper, or to the Oxford reptile. Mr. Hulke replied, pointing out that, since the determination of the Oxford reptile as *Cetiosaurus*, numerous other remains of the same species had been discovered, which had added materially to the basis of classification.—The following specimens were exhibited to the meeting:—Devonian fossils from the Witzenberg; exhibited by Professor T. R. Jones, F.G.S., in illustration of his paper. Specimens of Silver Ores from South America; exhibited by Professor Tennant, F.G.S. Fragment of the Wolf Rock, near the Land's End, and section under polarised light; exhibited by Mr. Frank Clarkson, F.G.S.

Royal Geographical Society, November 27.—Major-Gen. Sir H. C. Rawlinson, K.C.B., president, in the chair.—The President read a letter from Dr. Kirk, of Zanzibar, to the late Sir Roderick Murchison, giving news of a serious outbreak in Unyanyembe, the country lying on the main route to Lake Tanganyika, which is likely to prevent communication with Dr. Livingstone for some time to come. The letter was dated September 25th, and stated that a native chief, having been attacked by a force of Arabs settled in Unyanyembe, had waited his assailants in ambush when returning with their plunder, and had killed many of the principal men. Mr. Stanley, an American gentleman, who was travelling to Lake Tanganyika, and who had charge of letters and stores for Dr. Livingstone, was in the fray, and had been deserted by the Arabs. He had also been ill of fever, and his future plans were uncertain. A report, to which Dr. Kirk attached little credence, had spread in Zanzibar, to the effect that Livingstone and the Arab Mohammed bin Gharib, with whom he had been living, were returning round the south end of Tanganyika, and out of the region of disturbances. Captain R. F. Burton, in commenting upon this letter, informed the meeting that similar affrays between Arab trading parties and the natives had occurred before, and that this unsettled state might continue for two or three years. He thought that Livingstone would find no difficulty in returning by the south of the lake, and that a fearless man like him, speaking the native languages, would be able to pass through the disturbed districts. He had not the slightest misgiving with regard to him.—Captain Burton then read a paper "On the Volcanic Region east of Damascus and the Cave of Umm Nirân." This was a narrative of a hazardous journey of fifteen days, which he had performed in May and June 1871, in company with Mr. C. F. Tyrwhitt Drake, through the Safa Region, the Oriental *Trachon* of the Greek geographers, a wide extent of ancient lava-fields, the hills of which, like little pyramids, dot the eastern horizon, as viewed from Damascus. The danger and difficulty of visiting the many interesting places in this district arose simply from certain petty tribes of Bedouin, descendants of the refractory robbers of the Trachonitis, who dwell in the highlands of the Hauran, under the patronage of the Druses. The worst are the Ghiyās and the Shitāyā, who although they have given hostages, were allowed, during the author's stay at Damascus, to ride the country within three hours of the walls, and to plunder the villages. During one of his excursions a skirmishing party of Ghiyās attacked his party, severely wounding one of his companions. During his journey 120 inscriptions were collected, including three in the Palmyrene dialect. The volcanic outbreak to which the district

owes its singular character the author was inclined to attribute to the epoch when the Eastern Desert, a flat stoneless tract, extending from the Trachonitis to the Euphrates, was a mighty inlet of the Indian Ocean, having its northern limit in the range of limestones and sandstones, the furthest outliers of the Anti-Libanus, upon whose southern and eastern feet Palmyra is built, and which runs eastward to the actual valley of the great river. Mr. Drake took a continuous set of compass bearings during the journey, which had enabled him to draw an excellent map of the region. Mr. W. Giffard Falgrave spoke on the subject of the paper, stating that Captain Burton was the only European who had properly explored El Safi. He had himself explored about two-thirds of the distance, without, however, reaching the cavern of Umm Niran. His own visit terminated at the southern part of the *El Loja*, the great volcanic district celebrated for the destruction of the Egyptian army in the time of Ibrahim Pacha, when they attacked the Druses in the basaltic labyrinth.—A second paper was read, "On the Geography of Southern Arabia," by the Baron Von Maltzan, which contained interesting elucidations of the physical configuration and tribal distribution of the region north of Aden, compiled by systematic interrogation of Arabs at Aden.

EDINBURGH

Naturalists' Field Club.—The annual business meeting of this club was held on Wednesday, the 20th ult., when Mr. Skerving was elected President and Mr. John Brown Honorary Secretary and Treasurer. A vote of thanks was accorded to Mr. Taylor, the retiring secretary. The club now numbers 87 members; and 13 excursions have been made to places of local interest during the summer months.

PARIS

Academy of Sciences, November 27.—M. Chasles presented a theorem concerning the harmonic axes of the geometrical curves, in which there are two series of points corresponding anharmonically on a unicursal curve.—M. P. A. Favre communicated the continuation of his thermic investigations upon electrolysis, in which he gave the results of experiments made especially with the voltameter with plates of copper immersed in sulphate of copper.—M. de Fonville presented a note on musical sounds produced at the opening of the valve in balloon ascents.—M. des Cloiseaux communicated some optical and crystallographical observations upon montebasite and the ambygonite of Montebas, the former a new fluophosphate of alumina, soda, and lithia.—A letter was read from M. Moisson describing the use of sea-water for making bread in the environs of Cancale.—M. H. Sainte-Claire Deville presented a note by M. T. Schlösing on the separation of potash and soda. The author's process is founded upon that proposed by Serullas, in which perchloric acid is employed. He uses, instead of this acid, pure perchlorate of ammonia, treated with weak nitro-muriatic acid. The preparation of the perchlorate is described by the author.—M. Chabrier presented some further observations on the alternate predominance of nitrous and nitric acids in rain-water. The author finds that in calm weather nitrous acid is present in excess in rain-water, whilst nitric acid predominates in stormy weather.—M. Chevreul communicated a letter from M. Sacc on the properties of drying oils, with regard to which M. Thenard also made some observations.—A note by MM. Dussant and C. Bady on the phenoles was presented by M. Cahours.—M. C. Bernard communicated a note by M. E. Faivre on the movements of the sap through the bark. The author describes a series of experiments made upon mulberry trees, and demonstrates that it is in the bark, and particularly in its liber, that the ascending and descending movements of the sap take place.—M. Joseph-Lafosse presented some observations on the germination of seeds submerged in 1870-71 during the inundation of the neighbourhood of Carenton for the defence of Cherbourg. He stated that after the retirement of the water many plants sprang up in unusual abundance and vigour, and suggested that experiments should be made upon the effects of long soaking upon the germination of the seeds of useful plants.—A letter from M. A. de la Rive on M. Marey's recent communications relating to the electrical discharge of the torpedo was read. The author considered the action of the nerves in causing muscular contraction to be electrical, and that the electrical effect produced by the apparatus of the torpedo was caused by the accumulation in it of the energy of the immense multitude of nervous filaments with which it is supplied.—M. C. Bernard presented a note by M. L. Reverdin on epidermic grafting, describing and discussing the phenomena

produced by the transfer of portions of skin from one living animal to another. The author maintains that the adherence of these grafts is produced principally by the epidermis, the dermis having only a secondary action.—M. S. Meunier, in a note on meteoric metamorphism, described the transformation of amallite into chantonite by exposure for a quarter of an hour to a red heat, which confirms his conclusion that the latter is the eruptive form of the former.

THURSDAY, DECEMBER 14, 1871

THE COPLEY MEDALIST OF 1871

DR. JULIUS ROBERT MAYER was educated for the medical profession. In the summer of 1840, as he himself informs us, he was at Java, and there observed that the venous blood of some of his patients had a singularly bright red colour. The observation riveted his attention; he reasoned upon it, and came to the conclusion that the brightness of the colour was due to the fact that a less amount of oxidation sufficed to keep up the temperature of the body in a hot climate than in a cold one. The darkness of the venous blood he regarded as the visible sign of the energy of the oxidation.

It would be trivial to remark that accidents such as this, appealing to minds prepared for them, have often led to great discoveries. Mayer's attention was thereby drawn to the whole question of animal heat. Lavoisier had ascribed this heat to the oxidation of the food. One great principle, says Mayer, of the physiological theory of combustion, is that under all circumstances the same amount of fuel yields by its perfect combustion the same amount of heat; that this law holds good for vital processes; and that hence the living body, notwithstanding all its enigmas and wonders, is incompetent to generate heat out of nothing.

But beyond the power of generating internal heat, the animal organism can also generate heat outside of itself. A blacksmith, for example, by hammering can heat a nail, and a savage by friction can warm wood to its point of ignition. Now unless we give up the physiological axiom that the living body cannot create heat out of nothing, "we are driven," says Mayer, "to the conclusion that it is the *total* heat generated within and *without* that is to be regarded as the true calorific effect of the matter oxidised in the body."

From this again he inferred that the heat generated externally must stand in a fixed relation to the work expended in its production. For, supposing the organic processes to remain the same; if it were possible, by the mere alteration of the apparatus, to generate different amounts of heat by the same amount of work, it would follow that the oxidation of the same amount of material would sometimes yield a less, sometimes a greater, quantity of heat. "Hence," says Mayer, "that a fixed relation subsists between heat and work, is a postulate of the physiological theory of combustion."

This is the simple and natural account given subsequently by Mayer himself of the course of thought started by his observation in Java. But the conviction once formed that an unalterable relation subsists between work and heat, it was inevitable that Mayer should seek to express it numerically. It was also inevitable that a mind like his, having raised itself to clearness on this important point, should push forward to consider the relationship of natural forces generally. At the beginning of 1842 his work had made considerable progress; but he had become physician to the town of Heilbronn, and the duties of his profession limited the time which he could devote to purely scientific inquiry. He thought it wise, therefore,

to secure himself against accident, and in the spring of 1842 wrote to Liebig, asking him to publish in his "Annalen" a brief preliminary notice of the work then accomplished. Liebig did so, and Dr. Mayer's first paper is contained in the May number of the "Annalen" for 1842.

Mayer had reached his conclusions by reflecting on the complex processes of the living body; but his first step in public was to state definitely the physical principles on which his physiological deductions were to rest. He begins, therefore, with the forces of inorganic nature. He finds in the universe two systems of causes which are not mutually convertible;—the different kinds of matter, and the different forms of force. The first quality of both he affirms to be *indestructibility*. A force cannot become nothing, nor can it arise from nothing. Forces are convertible, but not destructible. In the terminology of his time, he then gives clear expression to the ideas of potential and dynamic energy, illustrating his point by a weight resting upon the earth, suspended at a height above the earth, and actually falling to the earth. He next fixes his attention on cases where motion is apparently destroyed without producing other motion; on the shock of inelastic bodies, for example. Under what form does the vanished motion maintain itself? Experiment alone, says Mayer, can help us here. He warms water by stirring it; he refers to the force expended in overcoming friction. Motion in both cases disappears, but heat is generated, and the quantity generated is the equivalent of the motion destroyed. Our locomotives, he observes with extraordinary sagacity, may be compared to distilling apparatus. The heat beneath the boiler passes into the motion of the train, and it is again deposited as heat in the axles and wheels.

A numerical solution of the relation between heat and work was what Mayer aimed at, and towards the end of his first paper he makes the attempt. It was known that a definite amount of air, in rising one degree in temperature, can take up two different amounts of heat. If its volume be kept constant, it takes up one amount; if its pressure be kept constant, it takes up a different amount. These two amounts are called the specific heat under constant volume and under constant pressure. The ratio of the first to the second is as 1 : 1.421. No man, to my knowledge, prior to Dr. Mayer, penetrated the significance of these two numbers. He first saw that the excess 0.421 was not, as then universally supposed, heat actually lodged in the gas, but heat which had been actually consumed by the gas in expanding against pressure. The amount of work here performed was accurately known, the amount of heat consumed was also accurately known, and from these data Mayer determined the mechanical equivalent of heat. Even in this first paper he is able to direct attention to the enormous discrepancy between the theoretic power of the fuel consumed in steam-engines and their useful effect.

Though this first paper contains but the germ of his further labours, I think it may be safely assumed that, as regards the mechanical theory of heat, this obscure Heilbronn physician in the year 1842 was in advance of all the scientific men of the time.

Having, by the publication of this paper, secured him-

self against what he calls "Eventualitäten," he devoted every hour of his spare time to his studies, and in 1845 published a memoir which far transcends his first one in weight and fulness, and, indeed, marks an epoch in the history of science. The title of Mayer's first paper was, "Remarks on the Forces of Inorganic Nature." The title of his second great essay was, "Organic Motion in its Connection with Nutrition." In it he expands and illustrates the physical principles laid down in his first brief paper. He goes fully through the calculation of the mechanical equivalent of heat. He calculates the performances of steam-engines, and finds that 100 lbs. of coal in a good working engine produce only the same amount of heat as 95 lbs. in an unworking one; the 5 lbs. disappearing having been converted into work. He determines the useful effect of gunpowder, and finds 9 per cent. of the force of the consumed charcoal invested on the moving ball. He records observations on the heat generated in water when agitated by a pulping engine of a paper manufactory, and calculates the equivalent of that heat in horsepower. He compares chemical combination with mechanical combination—the union of atoms with the union of falling bodies with the earth. He calculates the velocity with which a body starting at an infinite distance would strike the earth's surface, and finds that the heat generated by its collision would raise an equal weight of water $17,356^{\circ}$ C. in temperature. He then determines the thermal effect which would be produced by the earth itself falling into the sun. So that here, in 1845, we have the germ of that meteoric theory of the sun's heat which Mayer developed with such extraordinary ability three years afterwards. He also points to the almost exclusive efficacy of the sun's heat in producing mechanical motions upon the earth, winding up with the profound remark, that the heat developed by friction on the wheels of our wind and water-mills comes from the sun in the form of vibratory motion; while the heat produced by mills driven by tidal action is generated at the expense of the earth's axial rotation.

Having thus with firm step passed through the powers of inorganic nature, his next object is to bring his principles to bear upon the phenomena of vegetable and animal life. Wood and coal can burn; whence come their heat, and the work producible by that heat? From the immeasurable reservoir of the sun. Nature has proposed to herself the task of storing up the light which streams earthward from the sun, and of casting into a permanent form the most fugitive of all powers. To this end she has overspread the earth with organisms which, while living, take in the solar light, and by its consumption generate forces of another kind. These organisms are plants. The vegetable world indeed constitutes the instrument whereby the wave-motion of the sun is changed into the rigid form of chemical tension, and thus prepared for future use. With this prevision, as shall subsequently be shown, the existence of the human race itself is inseparably connected. It is to be observed that Mayer's utterances are far from being anticipated by vague statements regarding the "stimulus" of light, or regarding coal as "bottled sunlight." He first saw the full meaning of De Saussure's observation of the reducing power of the solar rays, and gave that observation its proper place in the doctrine of conservation. In the leaves of a tree, the carbon and oxygen of carbonic acid, and the hydrogen and oxygen of water, are forced asunder at

the expense of the sun, and the amount of power thus sacrificed is accurately restored by the combustion of the tree. The heat and work potential in our coal strata are so much strength withdrawn from the sun of former ages. Mayer lays the axe to the root of many notions regarding the vital force which were prevalent when he wrote. With the plain fact before us that plants cannot perform the work of reduction, or generate chemical tensions, in the absence of the solar rays, it is, he contends, incredible that these tensions should be caused by the mystic play of the vital force. Such an hypothesis would cut off all investigation; it would land us in a chaos of unbridled phantasy. "I count," he says, "therefore, upon assent when I state as an axiomatic truth that during vital processes the *conversion* only and never the *creation* of matter or force occurs."

Having cleared his way through the vegetable world, as he had previously done through inorganic nature, Mayer passes on to the other organic kingdom. The physical forces collected by plants become the property of animals. Animals consume vegetables, and cause them to reunite with the atmospheric oxygen. Animal heat is thus produced, and not only animal heat but animal motion. There is no indistinctness about Mayer here; he grasps his subject in all its details, and reduces to figures the concomitants of muscular action. A bowler who imparts to an 8-lb. ball a velocity of 30 feet consumes in the act $\frac{1}{10}$ of a grain of carbon. A man weighing 150 lbs., who lifts his own body to a height of 8 feet, consumes in the act 1 grain of carbon. In climbing a mountain 10,000 feet high, the consumption of the same man would be 2 oz. 4 drs. 50 grs. of carbon. Boussingault had determined experimentally the addition to be made to the food of horses when actively working, and Liebig had determined the addition to be made in the case of men. Employing the mechanical equivalent of heat, which he had previously calculated, Mayer proves the additional food to be amply sufficient to cover the increased oxidation.

But he does not content himself with showing in a general way that the human body burns according to definite laws, when it performs mechanical work. He seeks to determine the particular portion of the body consumed, and in doing so executes some noteworthy calculations. The muscles of a labourer 150 lbs. in weight, weigh 64 lbs.; when perfectly desiccated they fall to 15 lbs. Were the oxidation corresponding to that labourer's work exerted on the muscles alone, they would be utterly consumed in 80 days. The heart furnishes a still more striking example. Were the oxidation necessary to sustain the heart's action exerted upon its own tissue, it would be utterly consumed in 8 days. And if we confine our attention to the two ventricles, their action would be sufficient to consume the associated muscular tissue in $\frac{3}{4}$ days. Here, in his own words, emphasised in his own way, is Mayer's pregnant conclusion from these calculations:—"The muscle is only the apparatus by means of which the conversion of the force is effected; but it is not the substance consumed in the production of the mechanical effect." He calls the blood "the oil of the lamp of life;" it is the slow-burning fluid whose chemical force in the furnace of the capillaries is sacrificed to produce animal motion. This was Mayer's conclusion twenty-six years ago. It was in complete opposition to the scientific conclusions of his time; but eminent investigators have since amply verified it.

Thus, in baldest outline, I have sought to give some notion of the first half of this marvellous essay. The second half is so exclusively physiological that I do not wish to meddle with it. I will only add the illustration employed by Mayer to explain the action of the nerves upon the muscles. As an engineer, by the motion of his finger in opening a valve or loosing a detent, can liberate an amount of mechanical motion almost infinite compared with its exciting cause, so the nerves, acting upon the muscles, can unlock an amount of activity wholly out of proportion to the work done by the nerves themselves.

As regards these questions of weightiest import to the science of physiology, Dr. Mayer in 1845 was assuredly far in advance of all living men.

Mayer grasped the mechanical theory of heat with commanding power, illustrating it and applying it in the most diverse domains. He began, as we have seen, with physical principles; he determined the numerical relation between heat and work; he revealed the source of the energies of the vegetable world, and showed the relationship of the heat of our fires to solar heat. He followed the energies which were potential in the vegetable up to their local exhaustion in the animal. But in 1845 a new thought was forced upon him by his calculations. He then for the first time drew attention to the astounding amount of heat generated by gravity where the force has sufficient distance to act through. He proved, as I have before stated, the heat of collision of a body falling from an infinite distance to the earth, to be sufficient to raise the temperature of a quantity of water equal to the falling body in weight $17,356^{\circ}\text{C}$. He also found in 1845 that the gravitating force between the earth and sun was competent to generate an amount of heat equal to that obtainable from the combustion of 6,000 times the weight of the earth of solid coal. With the quickness of genius he saw that we had here a power sufficient to produce the enormous temperature of the sun, and also to account for the primal molten condition of our own planet. Mayer shows the utter inadequacy of chemical forces, as we know them, to produce or maintain the solar temperature. He shows that were the sun a lump of coal, it would be utterly consumed in 5,000 years. He shows the difficulties attending the assumption that the sun is a cooling body; for supposing it to possess the high specific heat of water, its temperature would fall $15,000^{\circ}$ in 5,000 years. He finally concludes that the light and heat of the sun are maintained by the constant impact of meteoric matter. I never ventured an opinion as to the accuracy of this theory; that is a question which may still have to be fought out. But I refer to it as an illustration of the force of genius with which Mayer followed the mechanical theory of heat through all its applications. Whether the meteoric theory be a matter of fact or not, with him abides the honour of proving to demonstration that the light and heat of suns and stars *may* be originated and maintained by the collisions of cold planetary matter.

It is the man who from the scantiest data could accomplish all this in six short years, and in the hours snatched from the duties of an arduous profession, that the Royal Society has this year crowned with its highest honour. Dr. Mayer had never previously received any mark of recognition from the society.

It was not in my power to be present at our late president's last address; but Sir Edward Sabine has done me the honour of sending me a printed copy of it. It contains the reasons assigned by him for the award of the Copley medal. Briefly, but appreciatingly, he expresses his opinion of the merits of Dr. Mayer, committing to Prof. Stokes the task of drawing up a fuller statement of the case. This statement is marked by an evident desire to act fairly towards Mayer, and at the same time to qualify the award so that no erroneous inferences may be drawn from it. It will be observed that Prof. Stokes confines himself to Mayer's first paper, the real value of which, however, is best appreciated in connection with Mayer's subsequent work, as the soundness of the root is best demonstrated by the vigour of the tree. Prof. Stokes writes thus:—

"In a paper published in 1842, Mayer showed that he clearly conceived the convertibility of falling force, or of the *vis viva*, which is its equivalent or representative in visible motion, into heat, which again can disappear as heat by reversion into work or *vis viva*, as the case may be. He pointed out the mechanical equivalent of heat as a fundamental datum, like the space through which a body falls in one second, to be obtained from experiment. He went further. When air is condensed by the application of pressure, heat, as is well known, is produced. Taking the heat so produced as the equivalent of the work done in compressing the air, Mayer obtained a numerical value of the mechanical equivalent of heat, which, when corrected by employing a more precise value of the specific heat of air than that accessible to Mayer, does not much differ from Joule's result. This was undoubtedly a bold idea, and the numerical value obtained by Mayer's method is, as we now know, very nearly correct." Prof. Stokes then qualifies the award in these words:—"Nevertheless it must be observed that an essential condition in a trustworthy determination is wanting in Mayer's method; the *portion of matter operated on does not go through a cycle of changes*. Mayer reasons as if the production of heat were the sole effect of the work done in compressing air. But the volume of the air is changed at the same time, and it is quite impossible to say *a priori* whether this change may not involve what is analogous to the statical compression of a spring, in which a portion or even a large portion of the work done in compression may have been expended. In that case the numerical result given by Mayer's method would have been erroneous, and *might* have been even widely erroneous. Hence the practical correctness of the equivalent obtained by Mayer's method must not lead us to shut our eyes to the merit of our own countryman Joule, in being the first to determine the mechanical equivalent of heat by methods which are unexceptionable, as fulfilling the essential condition that no ultimate change of state is produced in the matter operated upon."

The judgment of Prof. Stokes, regarding the possible error of Mayer's determination of the mechanical equivalent of heat, gives me occasion to cite another proof of the insight of this extraordinary man. His paper of 1845 contains the details of his calculation, which were omitted from his first brief paper. Mayer prefaces the calculation with these memorable words:—

"To prove this important proposition, we must fix our attention on the deportment of elastic fluids towards heat and mechanical effect.

"Gay Lussac has proved by experiment that when an elastic fluid streams from one receiver into a second exhausted one of equal size, the first vessel is cooled, and the second one heated, by exactly the same number of degrees. This experiment, which is distinguished for its simplicity, and which, to other observers, has always yielded the same result, shows that a given weight and volume of an elastic fluid may expand to double, quadruple, in short, to several times its volume without experiencing, on the whole, any change of temperature; or, in other words, that for the expansion of the gas of itself (*an und für sich*), no expenditure of heat is necessary. But it is equally proved that a gas which expands *under pressure* suffers a *diminution* of temperature.

"Let a cubic inch of air at 1° , and under the pressure of 30 inches of mercury, be warmed by the quantity of heat x to 274° C., its volume being kept constant; this air, on being permitted to stream into a second exhausted vessel of the same size, will retain the temperature of 274° , and a medium surrounding the vessel will suffer no change of temperature. In another experiment, let our cubic inch of air be kept, not at constant *volume*, but under the constant *pressure* of the 30-inch mercurial column, and heated to 274° . In this case a greater quantity of heat is required; let it be $x + y$.

"In comparing these two processes, we see that in both of them the air is heated from 0° to 274° , and at the same time permitted to expand from one volume to two volumes. In the first case the quantity of heat necessary was $= x$; in the second case $= x + y$. In the first case the mechanical effect was $= 0$; in the second case it was equal to 15 lbs. raised one inch in height."

He then proceeds with his calculation.

Here it will be seen that Mayer was quite awake to the importance of the considerations dwelt upon by Prof. Stokes—that he knowingly chose for his determination a substance which, *an und für sich*, in expanding, consumes no heat. Hence, when by its expansion *against pressure* heat is consumed, no part of that heat is lost in producing "a change of state in the matter operated upon." The heat consumed is, therefore, the pure equivalent of the work done.

With regard to Dr. Joule, I have, to my regret, vainly endeavoured to find a mislaid document written a year ago, in which I ventured to describe his labours,* and to express the esteem I entertain for them. Supposing him to have derived his inspiration from Mayer's papers, that they had even caused him to prosecute his experiments on the mechanical equivalent of heat, he would still have rendered immortal service to science, and more than merited the honours bestowed upon him last year. For, wanting his work, the mechanical theory, however strong the presumptions, and however concurrent the evidence in its favour, could not be regarded as completely demonstrated. But Joule was not stimulated by Mayer. His work is his own, being practically contemporaneous with that of Mayer. He not only demonstrated experimentally the mechanical theory of heat, but in its completer form he was an independent creator of that theory. And so impressed was the Council of the Royal Society last year with the magnitude of his

merits, that they actually added to the Rumford Medal already bestowed upon him, the final distinction of the Copley Medal. If England rated him as highly as I do, his reward would not be confined to mere scientific recognition.

As regards the latter, however, I do not think that the possibility suggested by Prof. Stokes represents any real danger. I do not imagine that the eyes of Science are in the least degree likely to be "shut to the merits of our own countryman." And I believe that the Royal Society, by stamping in two consecutive years these two men with the highest mark of its approval, will have strengthened that confidence in its impartiality which, throughout the whole scientific world, it has so long and so justly enjoyed.

JOHN TYNDALL

AIRY ON MAGNETISM

A Treatise on Magnetism. By G. B. Airy, Astronomer Royal. (Macmillan and Co.)

THIS is a book written upon the true scientific principle expressed by Newton when he said "*Hypotheses non fingo*." The elementary laws of magnetism are deduced by rigorous induction from particular cases and are then applied to explain phenomena. The book contains the substance of a series of lectures delivered by the Astronomer Royal at the University of Cambridge. One great element of excellence in the book is that the mathematics employed throughout are of a simple character, so that the first principles of magnetism are thus thrown open to one who has gone no great way in mathematical reading.

Formulae having been obtained in the early sections for the action of one magnet on another, and the law of the inverse square having been established by a comparison of calculation with experiment, the great bulk of the volume is occupied in investigations which bear more directly on terrestrial magnetism and the magnetism of iron ships. The methods of determining the values of the magnetic elements at any place are carefully explained and illustrated, and the necessary formulae deduced from the theory established in the preceding sections. We would especially recommend to the reader's attention the articles on the theory of the dipping needle. One chapter of extreme interest is devoted to "Theories of Terrestrial Magnetism," and the beautiful theory of Gauss is sketched out. We sincerely hope that that theory which was carried by Gauss to the fourth order of approximation will be before long carried to a higher order. Data now exist for this advance, as it requires accurate determinations of only eleven more elements.

The subject of the deviation of the compass in iron ships is one upon which the Astronomer Royal is peculiarly justified in speaking or writing. All the sections relating to the disturbance of compass needles are full of most important and suggestive matter. One section is devoted to the continuous registration of small changes in terrestrial magnetism, and the concluding section just touches on the subject of the relation between galvanic currents and magnetic forces, without entering into any calculations.

The book supplies a distinct want which has hitherto existed in the list of our mathematical text-books, and is a most valuable contribution to the diffusion of physico-mathematical science.

JAMES STUART

* Thanks to the friendly efforts of Dr. Sharpey, this document reached my hands just as the proof of this paper was being returned for press. With the permission of the Editor of NATURE I will publish the document, with some additional matter, next week.

OUR BOOK SHELF

Rudimentary Treatise on Geology.—Part II. Historical Geology. By Ralph Tate, A.L.S., F.G.S., &c. With Illustrations and an Index. (London: Lockwood and Co.)

THIS little book is partly based on Portlock's "Rudiments of Geology," and "is set forth in the full belief that it will be found to be an epitome of the history of the British Stratified Rocks." The first three chapters are introductory, and contain the usual table of the British Sedimentary Strata, with some brief remarks thereon, which are followed by what the author calls a "Palæontological Summary." In this summary he takes a rapid view of the animal and vegetable kingdoms, and points out briefly under which classes and orders fossil organic remains may be ranged. The rest of the volume is entirely occupied with descriptions of the Formations and their subdivisions, and with lists of characteristic fossils. We have no doubt that the preparation of this book has cost its compiler considerable labour; and he certainly has managed to cram a good deal into the short space at his command. The information, indeed, is just too tightly packed; it forms very dry reading, and will be apt to frighten a beginner. If it was necessary that the volume should be no larger than it is, we think some of the palæontological details might have been omitted, and here and there the description of minor subdivisions of formations conveniently cut even shorter than they are, so as to obtain room for certain particulars about the history of the strata, which are either too meagrely noticed or are altogether ignored. The references to former volcanic action in Britain are quite inadequate. We find no mention of the fact that volcanoes were active in the South-West of England during the deposition of the Devonian Strata; nor is there any notice taken of the occurrence of volcanic rocks in the Old Red Sandstone of Ireland. A slight allusion is made to the igneous rocks of the Scottish Middle Old Red Sandstone, but the far more extensive volcanic products belonging to the Lower Old Red series are passed over altogether. The igneous rocks of the Pentland Hills are not, as the author states, of "Upper," but of Lower Old Red Sandstone age. Again the reader, looking over what is said about the igneous rocks of Carboniferous age, would never learn that volcanoes played so active a part in Scotland during the accumulation of the Lower Carboniferous and Carboniferous Limestone periods; nor that in Ireland also volcanoes here and there piled up ejectamenta upon the bed of the Carboniferous Limestone sea. Surely in a book purporting to be an epitome of the history of British stratified rocks, the volcanic phenomena that characterise so many successive epochs of the past ought to have had a somewhat fuller notice. There are various other points in connection with physical geology which are quite ignored. For instance we find no mention of Prof. Ramsay's theory of the Glacial origin of certain breccias and conglomerates of Silurian, Old Red Sandstone, and Permian age—a theory which, whether Mr. Tate agrees with the Professor or not, ought certainly to have had some reference made to it no matter how brief. We had marked a number of passages where the author's meaning is not very clear and will be apt to puzzle a learner. One of these will suffice. Speaking of the Glacial epoch, the author says:—"Our inquiry has now come to that point where, though we still see in the recent results of geological phenomena evidence of the formative processes of nature, yet we are kept at a distance from the present epoch; for although the shells are all of living species, they are generally arranged in positions and associated with detrital matters of such a description that their appearance indicates the action of forces prior to the present order of things." Occasionally we come across statements which are very far from being consistent "with the opinions generally

held by geologists." We read, for instance, that "the first trace of a land plant is at the very top of the Upper Silurian, and we may conclude that there were no terrestrial plants during the long Silurian epoch, a vast interval far exceeding in duration that of any other system."

Besides figures of characteristic fossils, the volume is illustrated with a number of diagrammatic sections. A copious index is appended. J. G.

Illustrated Catalogue of the Museum of Comparative Zoology at Harvard College. No. IV. Deep-sea Corals. By L. F. de Pourtales, Assistant U.S. Coast Survey, 1871.

COUNT POURTALES had the good fortune to be one of that band of naturalists who, dredging for the first time in deep water between Key West and Havana, came to the conclusion that "animal life exists at great depths in as great an abundance as in shallow water." This opinion was published in his "Contributions to the Fauna of the Gulf Stream at great Depths" (Cambridge, U.S., 1867). Moreover as a zoophylogist he had the credit of obtaining the first true stony corals from great depths. Numerous corals were dredged up under his superintendence in 1868 and 1869 from off the sea floor of the so-called Straits of Florida in the course of the Gulf Stream, and they were carefully described by him in Nos. 6 and 7 of the last-mentioned work. Now the results of the Deep-sea Dredging so far as the Corals are concerned, appear in the handsome essay in quarto before us; the specific descriptions have been revised, new forms are described, and the illustrations in lithography testify to the excellence of American printing from stone. The interesting coral fauna in the deep sea of Florida has already to a certain extent been compared with that of the cold and warm area of the North Atlantic, in the Proceedings of the Royal Society, March 24, 1870; and the new species described by M. de Pourtales, together with the remarks upon the classification of the corals, will probably enhance the importance of the labours of those English naturalists who have undertaken the description of the results of our abyssal dredgings. The great horizontal range of some of the deep-sea corals is as remarkable as the vertical range of others; and M. de Pourtales, although strongly impressed with the importance of some structural characters in the distinction of specific differences which are not thought so valuable and important in England, leans to the belief in these ranges. The American deep-sea coral fauna is not so rich in species, and apparently in individuals, as that of the North Atlantic and Lusitanian Coasts, but there is one form which is found in the globigerina mud off Bahia Honda, Florida, in 324 fathoms, which will always be of interest to the naturalist who studies palæontology. *Haplophyllia paradoxa* Pourtales, possesses all the essential characters of the Rugosa, and is allied to the simple coral, *Calophyllum profundum* Gernar—the Permian *Polycaulia profunda* of King, but it has been shown to be also allied to *Guyonia annulata* Duncan, a small rugose coral dredged off the Adventure Bank in the Mediterranean. Both *Haplophyllia* and *Guyonia* have a strong central axis or columella, the existence of which is of generic importance, and it is therefore necessary to ally these two modern representatives of the old Rugosa which dominated in the coral fauna of the Palæozoic age with the Cyathaxonidæ of the Carboniferous rocks. M. de Pourtales is so gentle a critic that if one wished to differ from him in print, the desire would fail. When the Zoological Society print, which they are about to do, the Essay on the deep-sea corals dredged from H.M.S. *Porcupine*, nothing will be more satisfactory than that an interchange of notes and specimens should take place, so that in a supplement the American and English authors may terminate their unimportant little differences in classification. The beauty and correctness of the illustrations are extreme, and they do the artist, and especially the printer, great credit. It

is to be hoped that some English lithographic printer will see the American triumph in this particular, and will forthwith mend his ways. P. M. D.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Alternation of Generations in Fungi

IN Mr. Cooke's article on this subject, it is stated that I have shown that there are at least four consecutive forms of reproductive cells in the bunt (*Tilletia caries*). I imagine that by slip of the pen he must have substituted this for hop mildew; but, be this as it may, what I really did say at a time (1847) when the formation of secondary fruit was not ascertained in Ustilago, Puccinia, and allied parasites, was as follows, after describing the curious anastomosing threads which are produced on the germinating processes of the bunt spores:—"I was at first inclined to think that it had something to do with the reproduction of the bunt, and it is quite possible that in plants, as well as in the lower animals, there may be an alternation of generations. This is, however, merely thrown out as a hint which may be followed out by those who have fewer avocations than myself. Many anomalous appearances, amongst Algae especially, seem to indicate something of the kind."* This growth can only be regarded as an intermediate state, which is probably necessary for the propagation of the parasite, and the same must be said of other cases in which the anomalous form does not produce organisms similar to itself. In such cases as the hop and vine mildew, the Oidium forms may be propagated almost indefinitely with only an occasional production of another form, and this, perhaps, may safely be regarded as an alternation of generations, while mere conidia-bearing forms can scarcely be so regarded. In such cases as that of the Uredos, which accompany or precede Puccinia, though both are fertile, we can scarcely recognise such an alternation; but if it is once established that a Puccinia produces an *Æcidium*, or an *Æcidium* a Puccinia, we should have a clear case. The usual argument about wheat being subject to mildew where there are no berberry plants, or Roestelia where there are no savines, does not seem to me to be good. It appears quite clear that wheat mildew may be produced, either from the germination of *U. rubigo vera*, or from its own secondary spores, and that almost indefinitely, where there is no berberry; but this does not show that the spores of Puccinia, when sown on the berberry leaf, may not produce the *Æcidium*, or the spores of the *Æcidium* the mildew. I quite agree with Mr. Cooke, that the observations of Oersted and De Bary are not absolutely conclusive, though I may be inclined to give them more weight than he does. The observations should certainly be repeated; but, if the results should be the same, I should certainly feel inclined to accede to their views, in despite as I always am either to jump hastily to conclusions myself, or to accede at once to the crude observations of others. M. J. BERKELEY

WHETHER Mr. Cooke has sufficiently appreciated the labours of De Bary and Oersted, in his article published in your columns of last week under the above title, I leave for others to determine. I wish now merely to call attention to one sentence in his article, as follows:—"It is manifest that no amount of care in cultivation, under bell glasses or other exclusion from foreign influences, is sufficient against a contingency which dates back to the seed of the nurse-plant." Does Mr. Cooke mean that the spores of the fungi themselves deposited in the seed of the nurse-plant are carried up, so to speak, in the process of growth, into the leaves, where they germinate; or that the liability to produce parasitic fungi is communicated from the seed to the mature plant by some process which combines the Pangenesis of Darwin with the spontaneous generation of Bastian? I see no other explanation of the sentence than one or other of these alternatives.

MYCELIUM

Leibnitz and the Calculus

PROF. TAIT need not wonder if an attack that is "totally unexpected" should seem "appallingly sudden." In the absence of a statute of limitations restricting to two years and a half

the right to take up a gage, there can be no reason why an attack should not be made, save its personal bearings; and the circumstances of the challenge might be cited in bar of any exception taken on that ground. I thank the Professor for his explanations. I could not have guessed that under cover of his challenge to produce a metaphysician who was also a mathematician, lurked the assumptions, that every mathematician was a metaphysician, and that every metaphysician was either a mathematician or (in the old sense) a physician. Well, he has a perfect right, for his own private convenience or pleasure, to identify two names which he had from the first asserted to be eternally distinct. Accepting his classification, then, for the sake of argument—certainly not for fruitless controversy—to wit, that everyone is either a mathematician or a non-mathematician, and that every true metaphysician must be either mathematician or physician (Faraday did not hate the term "physicist" worse than I do) we are confronted with some surprising results. Leibnitz, the author of the *Monadologie* and the *Theodicee*, works that are known to contain the germs of the *Kritik der reinen Vernunft*, was a *spurious* metaphysician. Why, in the name of common sense? "Because," says Prof. Tait, "he was a non-mathematician; there is no medium, you know; he must have been either a non-mathematician or a mathematician, and a mathematician he was not." What! Leibnitz not a mathematician? "Not a bit of it," says Prof. Tait; "for he was, I fear, simply a thief as regards mathematics, and in physics he did not allow the truth of Newton's discoveries." I do not object to the Professor calling a spade a spade; but I assure him that this charge is made just twenty years too late. It is exactly that time since the last vestige of presumption against the fair fame of the great German was obliterated. If Prof. Tait does not understand me, or, understanding me, disputes the unqualified truth of my statement, I promise to be more explicit in a future letter. But I incline to think the question is not susceptible of proof until the Council of the Royal Society, who so grossly disgraced themselves in 1712, shall do the simple act of justice and reparation required of them, viz., publish the letters and papers relating to this controversy, which since that date have slumbered in the secret archives. I advise Prof. Tait to utilise the meantime by reconsidering some of his utterances on the *Principia*, lib. ii. lem. 2.

It appears, too, that Descartes, notwithstanding his physics, which are very sad, was a mathematician, and therefore a *true* metaphysician, and this, I suppose, despite the *spurious* metaphysics of his *Discours* and his *Meditations*. By the way, when Prof. Tait parenthetically and admiratively corrects me for calling him *Cartes*, he surely overlooked the fact that *Cartes* is his English name, the name by which he was known to the readers of Dr. Samuel Clarke, &c., and is therefore preferable to the dog-latin alternative.

Such, then are some of the surprising results of adopting Prof. Tait's classification of mathematicians and metaphysicians. But he objects to my classification of the former, that the greatest mathematicians of our own day—among which Prof. Tait will allow me to count himself—would fall into my second class, since they are not inventors of a calculus, and yet they are not mere experts. Among the names he adduces are Cayley and Sylvester, the co-inventors of a new calculus, viz., that which has been so fertile in its application to Linear Transformations; I mean, of course, the Higher Algebra. Accordingly, both would, of course, fall into my first class; and I will add, that I should assuredly think that "something is rotten in the state of Denmark" if I found the true mathematical *σοφιστής* had ever contented himself with the improvement and application of other men's productions. C. M. INGLEBY

Highgate, Dec. 4

The Science and Art Department

I HAVE been expecting, but in vain, to see Mr. Uhlgren's reply to the request made to him a few weeks since, to produce the Department's letter of which he spoke, and in which it was stated that the rumoured reduction of the number of certificates awarded had actually taken place through the examination papers having been returned for revision. I quite agree with your correspondent who challenged its production, that such a document ought to be made widely known if it exists; whereas if Mr. Uhlgren's statement is founded on any misapprehension, it ought to be corrected without delay.

If such a statement were ungrounded, such complaints as those Mr. U. made are, I think, more likely to damage the cause of

* "Journal of Horticultural Society of London," vol. ii. p. 112.

science teachers, who have already enough grievances to urge against the Department on the score of its administration, than to obtain any amelioration of their status.

I do not think many science teachers will endorse more than one other of Mr. Uhlgren's complaints; so that it is of the greatest importance that that one which affects them all should be proved in the fullest and most circumstantial manner.

Plymouth, Dec. 9

A LOCAL COMMITTEE-MAN

Lunar Calendars

I WISH to call attention to the variations observable between the true period of new moon and the commencement of lunar months, as set forth in the following table:—

Period of New Moons	Jewish Calendar	Mahomedan Calendar
A.D. 1872 H.M.	A.M. 5632-3	A.H. 1288-9
Jan. 10 2 58 P.M.	Shebat commences 11	Jan. 12 Dulkadad
Feb. 9 1 52 A.M.	1st Adar " 10	Feb. 11 Dulhagee
Mar. 9 6 53 P.M.	2nd " " 11	Mar. 11 Mulharam
April 8 6 32 A.M.	Nisan " 9	April 10 Saplar
May 7 1 19 P.M.	Iyar " 9	May 9 Rabia (i.)
June 6 3 23 A.M.	Sivan " 7	June 8 " (ii.)

Dec. 30 6 35 P.M.	Kislev " 1	Dec. 2 Shawal
Dec. 30 6 36 A.M.	Tebeth " 31	31 Dulkadad

As many eminent and practical astronomers write to NATURE, I shall be much obliged if one will add a fourth column to the above, fully explaining these differences. My object is to ascertain if a calendar, founded on lunations, is at all susceptible of *universal* use, so as to be correct to time in all places. The true new moon is *invisible*, the visible new moon is not the true new moon; is there a medial average?

November 23

MYOPS

New Zealand Forest Trees

LET me recommend those of your readers who take an interest in this subject, to trust for *correct* information thereunto the works whose names are appended, and *not* to the statements of recent correspondents of NATURE, who commit errors so great as to refer *Manuka* to the genus or family *Diosma*!

- (1) Dr. Hooker's "Handbook of the New Zealand Flora," which contains at the end of vol. ii. an "Alphabetical List of Native and Vernacular Names" of New Zealand plants, including trees.
- (2) A similar Catalogue of Native and Vernacular Names, published, subsequently to Dr. Hooker's list, by Dr. Hector, Director of the Geological Survey of New Zealand.
- (3) "Report and Award of the Jurors" of the New Zealand Exhibition of 1865; which contains at page 474 an admirable table—showing the strength and other qualities of New Zealand woods, in connection with the names of the trees yielding the said timbers—carefully drawn up by the late Provincial Marine Engineer of Otago, J. M. Balfour, C.E.; and
- (4) The 3 vols. already published of the "Transactions and Proceedings of the New Zealand Institute."

W. LAUDER LINDSAY

Solar Halo

SEEING in your last number an account of a Solar Halo, it has occurred to me that the following description of a similar phenomenon, which I saw in Norway this autumn, may not be uninteresting to some of your readers.

The sun, at 4 o'clock P.M., was just setting behind a range of mountains in the Romsdalen, when a bright halo of light appeared round it, forming a clearly-defined circle, and at the crown of the circle there appeared two horns, as of the beginning of another circle inverted, the junction of the two circles being very luminous; the limbs of the inverted circle—if I may so call it—were rather straight than curved, and were not very long. A

second and outer circle, just twice the diameter of the inner one, shortly appeared, and this circle had all the colours of a rainbow most distinctly visible. These two bows were strongly defined for an hour at least, and during that time constant waves of light shot up and across the sky, not always from the centre, where the sun was, but often from some point within the inner circle to the south of its centre. At other times rays of light would shoot out at a tangent from the outer bow, sometimes on one side and sometimes on the other. Again, some would shoot from one circle to the other, forming a series of bars parallel with the horizon, and at last the rays seemed to concentrate, and radiating from the centre of the inner circle, shot right through both circles across the sky over our heads, forming a series of gigantic ribs, which extended from west to east.

The day (it was September 23) had been perfect, with a bright sun, a cold, frosty atmosphere, and a blue, cloudless sky. Snow had fallen heavily about three days before, and was still lying everywhere; but on the day we saw this grand display not a cloud had been visible from morning till evening. After all was over, the clouds crept up, and we saw several brilliant shoots of the Northern Lights.

W. W. HARRIS

Manningham, Bradford, Dec. 6

Proof of Napier's Rules

SUCH a structure in cardboard as that described by Prof. A. S. Herschel in NATURE, No. 106, may be found very useful in facilitating the study of the proof of "Napier's Rules," but the ingenious learner might object that the demonstration was confined to one particular species of triangle—the isosceles right-angled with a perimeter equal to a quadrant; for Mr. Herschel's angles a and b are plainly equal, and together with c make up a right angle. The corresponding construction for any case would be as follows:—Take a circular piece of cardboard with centre D (referring to Mr. Herschel's diagram), and on the circumference, in the same direction, take any two arcs B1, 12. Let a perpendicular from B or D1 meet it in D, and a second from C or D2 meet it in A, and be produced to reach the circumference in B'. Finally, a semicircle on A B' as diameter and another with centre A and radius A C will determine by their intersection the point C'. To a construction thus generalised all that Prof. Herschel adds would apply.

As a question of "Queen's English," it seems hard to connect the last clause in the first paragraph of Prof. Herschel's letter with what precedes. "Then" can only refer grammatically to "difficulties;" but surely Mr. Cooley did not propose to himself "to render them as easily accessible as possible to the inquiring student in mathematics."

J. J. W.

The Cause of Specific Variation

I HAVE only just read Mr. Mivart's "Genesis of Species," and was glad to find that his ideas, so ably expressed, are nearly, if not quite, identical with my own, which I laid before the Victoria Institute in a paper "On Certain Analogies between the Method of Deity in Nature and Revelation," May 10, 1869. On p. 259 of his "Genesis of Species" he has the following remarks:—"But are there any grounds for thinking that, in the Genesis of Species, an *internal* force or tendency intervenes, co-operating with and controlling the action of external conditions?" This question appears to me to exactly correspond with the sentiments of the following passage from the "Journal of the Transactions of the Victoria Institute," vol. iv., p. 265:—

"Rather than venture on any attempt to explain the Divine methods by ordinary terms, I would prefer adopting some general expressions to convey an imagined idea of the causes of existing things, and as less liable to the charge of anthropomorphism.

"I purpose, therefore, adopting the general word *force*, and recognising all issues in nature as the effect produced upon matter by the resultant of component forces. These forces are separable into physical, chemical, biological, &c.; and, in addition to all those which the chemist and the physicist can eliminate and claim as the objects of their special studies, there still remains a residuum of forces in those organisms endowed with life, and which produce those results which we say are designed, and which it is customary to regard as witnessing to a Divine Intelligence.

"In recognising these latter forces, I would call them *evolution*, but as being so far like others that their resultant with them produces relative effects only according as in their continual

attempt at equilibration they are more or less counteracted or assisted by other natural forces.

"As an illustration I would recognise every special issue of evolution, as, for example, some well-marked variety of animal (say pigeon) or plant (say rose) as the effect of the combination of the usually so-called natural forces in conjunction with the evolutive, as a temporary stable form, so long as environing conditions to which it was subjected remain the same. Hence appears the permanency of some species and races. Subject them, however, to altered conditions, and thus bring an unaccustomed set of forces to bear upon them, *e.g.*, by domestication or cultivation; the forms once so stable soon 'break,' the equilibrium is overthrown, and variations once more ensue.

"After all, therefore, what I have here called evolutive forces in the organic world may prove to be only particular phases of those which conspire to constitute animal and vegetable life. And just as in the vital force itself it is usual to recognise two such phases, *viz.*, the vegetative and reproductive, so the power of development or continual advance or alteration from an assumed type may ultimately appear as particular forms of life-force issuing in those results which we are accustomed to look upon as designed."

GEORGE HENSLOW

ON DEEP-SEA THERMOMETERS*

THE objects of this paper and of the experiments and observations recorded therein, are:—

1. The ascertainment of the effect of pressure on thermometers used for deep-sea purposes.

2. To obtain a scale whereby observations made by the thermometers now in use could be corrected for pressure.

3. To obtain a scale whereby observations made previously by other thermometers can be utilised.

In the early part of the year 1868 the attention of the Hydrographer of the Navy was directed to the unsatisfactory nature of the deep-sea Six's thermometers then in use.

The objections made to these thermometers were:—

1. Their fragility, the slightest jar or blow often breaking them.

2. The necessity of their being always kept in a vertical position.

3. The uncertainty of the register, the indices being generally capable of being shaken down.

4. Their large size, in connection with friction in passing through the water.

5. The substance they were mounted on, being generally wood, became so swollen by pressure of the water as often to render them incapable of being withdrawn from the case.

It was also considered that in all thermometric observations at great depths we had been "working in the dark," in that we had no idea of the effect pressure had on the instrument, and consequently on the recorded results; and it was reasonable to suppose that as the action of a thermometer was affected *in vacuo*, an opposite effect would be had by placing them under pressure, the more especially as in the one case the pressure of only one atmosphere, or 15 lb. to the square inch, was removed, while in the other the atmospheres would have to be reckoned by hundreds and the pressure by tons. On this point we were not without actual observation; for Mr. Glaisher, during the year 1844, in some experiments made on the temperature of the Thames near Greenwich with delicately constructed instruments, found that the indications of temperature were affected by pressure on the bulb of the thermometers, and that at a depth of only 25 feet, or about three-fourths of an atmosphere, the readings were increased by 2°; but no definite conclusion could be arrived at from these observations in respect to our deep-sea thermometers, beyond the fact that they were liable to be so affected.

It was therefore suggested to the Hydrographer—

1. That the author might be placed in personal communication with different makers in respect to the best construction for the purpose required; and

2. That a series of experiments should be made by placing some thermometers in a hydraulic press in conjunction with one in an hermetically sealed iron bottle (as a standard) and subjecting them to pressure, that they should be kept under pressure sufficient time to allow the thermometer within the bottle to take up the temperature without, and then the whole compared with the standard.

The first suggestion was immediately acceded to; and those makers from whom the Meteorological Department obtained instruments were applied to, and a list of desiderata submitted to each. Three makers responded, and six instruments were ordered from each.

These instruments were sent in (hereafter called the Hydrographic Office pattern), and Mr. Balfour Stewart, of the Observatory at Kew, was consulted as to the *modus operandi* of testing by pressure, and he approved of that already suggested.

A difficulty arose in respect to a hydraulic press—the use of some in London could not be obtained, and others were not adapted to the purpose, so that the testing was deferred, and some of the instruments were sent to H.M.S. *Gannet*, then deep-sea sounding on the edge of the Gulf-Stream, and afterwards some to H.M.S. *Lightning* for her dredging cruise.

On the return of these vessels the conflicting nature of the temperatures obtained from those supposed to exist (as derived from observations in other localities) rendered the necessity of ascertaining the nature and amount of error due to pressure the more imperative.

At this juncture Mr. Casella undertook to have a testing apparatus constructed at his own expense, capable of producing a pressure of three tons to the square inch.

At a meeting of the Committee of the Royal Society, held in the Hydrographer's Room in April, 1869, and at which the plan of operation for testing the thermometers was discussed, that by means of an iron bottle approved. The late Dr. Miller, V.P.R.S., proposed encasing the full bulb in an outer covering of glass containing air, in order to permit the lighter fluid (air) to be compressed without affecting the bulb within, and one such was directed to be made; but instead of the outer casing being filled with air it was nearly filled with alcohol, which being heated to reduce the quantity of air, the bulb was then hermetically sealed. Mr. Casella was also directed to make others that would facilitate the observations.

At the time these experiments were proposed, it was not known that a thermometer had been constructed, at the suggestion of Mr. Glaisher, by the late Admiral Fitzroy's directions, with the view of removing the difficulty of pressure; this was done by encasing the long bulb at the back of the instrument in glass, and nearly filling the space between the case and the bulb with mercury; and one on this principle was then in the Instrument-room of the Meteorological Office; but although some had been used for deep-sea purposes, the further issue of them had been stopped on account of their fragility, and thus the means for obtaining accurate observations were virtually the same as before.

It was decided to test them at pressures equal to the following depths in the ocean, *viz.*, 250, 500, 750, 1,000, 1,250, 1,500, 1,750, 2,000, 2,250, and 2,500 fathoms, the rule to be applied being 33 feet = one atmosphere = 15 lb. on the square inch. From this a table was constructed for use.

On the 4th of May the following thermometers were taken to Hutton Garden, *viz.* :—

Nos. 56 and 57	Casella	Hydrographic Office pattern.
66 and 67	Elliott	" " "
72 and 73	Pastorelli	" " "

* See Meteorological Papers, No. I., 1863.

* Abridged from a paper read before the Meteorological Society, April 19, 1871, by Capt. J. E. Davis, R.N.

No. 1	Casella .	Specially made with an extra-thick cylinder bulb to defy compression.
3	" .	Spherical bulb; extra-thick glass. This thermometer was made, at the special request of one of Mr. Casella's workmen, in order to resist effect by pressure.
4	" .	Short cylinder bulb: extra-thick glass.
6	" .	A glass cup fitting over bulb, designed by Mr. Siemens.

All the above were Six's thermometers with the bulbs unprotected.

No. 2	Casella .	Glass-encased bulb, as proposed by Dr. Miller, but with the case nearly filled with spirit.
5	" .	Long cylinder bulb at the back, encased in glass, and nearly filled with spirit.

These instruments were first compared in air and then immersed in a tub of water, No. 57 being placed in an iron bottle. Set the indices and placed the thermometers in the cylinder of the press, and pumped on a pressure equal to 250 fathoms, and kept it on two hours.

It is useless to record the result of this first experiment; or it may rather be stated that the results were *null*, except ascertaining the weak points of the process adopted.

The Miller-pattern thermometer subsequently proved so near perfection it was decided to use that as a standard for the Hydrographic Office pattern.*

It was found necessary to reduce the number of thermometers, and also of the readings, to a minimum.

With the view of testing the efficiency of Dr. Miller's pattern (No. 2) it was placed in the cylinder with No. 57, and subjected to a pressure of 4,032 lbs. (about 1,480 fathoms) for a quarter of an hour, with the following result.

EXPERIMENT NO. 1 (pressure = 1,480 fathoms).
Dr. Miller reading.

Thermometer.	Minimum.		Maximum.		Diff. of Max.
	Before.	After.	Before.	After.	
2	47°5	47°5	47°5	48°0	0°5
57	47°5	47°5	47°5	55°0	7°5

This experiment at once proved the efficacy of the encased bulb; and the experiment was repeated with more thermometers, with the same pressure and for the same period of time.

It was found by this experiment that while the mean difference of the encased bulbs was only 0°·05, that of the two made to defy compression was 7°·25, that with the cover 10°·5, the Hydrographic Office pattern the same as in No. 1, 7°·5, and a Phillip's Alpine thermometer 70°·3.

The "Phillip's" was an ordinary make, with a very small bulb; and the great difference shown by it proved that the amount of compression is in proportion to the thickness of the glass; but in immediate connection with the subject the experiment clearly demonstrated two facts, viz.:

1. That very nearly all the difference, or error, is due to pressure on the full bulb; and
2. That by encasing the bulb we have nearly a perfect instrument.

Notwithstanding the satisfactory result obtained in enabling us to decide on a thermometer for future use, it was necessary, if possible, to establish a scale whereby temperatures already taken with instruments of the Hydrographic Office pattern might be corrected for pressure, and also to ascertain if all, or what part, of the difference shown under pressure in the Miller pattern was due to calorific effect produced by sudden compression of the water in the cylinder or by compression of the unprotected parts: preparation was accordingly made to continue the experiments.

It being necessary, as before stated, to reduce the number of the thermometers, and also the readings, to a minimum, the following were selected, viz.:

Nos. 2 and 5	Casella .	Encased bulbs.
56 and 57	" .	Hydrographic Office pattern.
73	Pastorelli	" " "
67	Elliott	" " "
9641	Casella .	Alpine.

These were attached to a float (to avoid immersing the hand in the water) and placed in the cylinder filled with water, to remain all night; the cistern, from which the water is pumped into the cylinder, was filled, and also a tub of water for replenishing placed by the side in order that the water in each might be, as nearly as possible, of the same temperature in the morning.

The thermometers were read in the order in which they are placed; when all were read, the indices were set as quickly as possible, and the instruments at once lowered into the cylinder and the pressure applied.

May 5. The first series of experiments were made, Mr. Casella reading.

FIRST SERIES OF EXPERIMENTS. Errors at different pressures. (*Abridged from original.*)

Thermometer.	No. 1. 250 fms. 682 lbs.	No. 2. 500 fms. 1,363 lbs.	No. 3. 750 fms. 2,045 lbs.	No. 4. 1,000 fms. 2,728 lbs.	No. 5. 1,250 fms. 3,400 lbs.	No. 6. 1,500 fms. 4,083 lbs.	No. 7. 1,750 fms. 4,771 lbs.	No. 8. 2,000 fms. 5,452 lbs.

Phillip's Alpine . . .	...	...	...	...	...	...	...	71°0
Thomson §.	...	...	...	...	...	...	...	1°1

* I was not aware at that time of the existence of the enclosed Phillip's thermometer as designed by Sir William Thomson.

† The instrument was taken out safely, but while reading off the full bulb cracked right across.

‡ Broke at a pressure equal to 1,848 fathoms.

§ This insulated thermometer is a Phillip's encased in a glass cylinder containing a little spirit, designed by Sir William Thomson.

The thermometers were under pressure for an average time of 37 minutes in each experiment.

May 6.—The following experiment was made with the Hydrographic Office pattern (not used yesterday) for comparison. Mr. Casella reading.

Pressure = 2,000 fathoms = 5,452 lbs. Under pressure seventeen minutes.

Thermometer.	Error.
2	1'4
5	1'2
53	9'9
58	10'7
71	11'3
74	10'3
75	9'6
Thomson	1'0

SECOND SERIES OF EXPERIMENTS

June 21.—The thermometers were placed in the

cylinder, which was filled with water; the supply-tub or cistern for pumping in from, and a tub of water standing near the press, were also filled and thus left all night.

June 22.—A dull morning, with no sun, and all conditions most favourable for observing.

Before commencing, obtained two tubs of water with 12° difference of temperature, and tested the thermometers as to time in taking up heat and contrariwise, and it was found that, by allowing the thermometers to remain under pressure eight minutes, the same results would be obtained as if they were allowed to remain half an hour or more, as in the first series of experiments.

The thermometers used were—

Standard . . .	Casella .	Dr. Miller's pattern.
No. 54 . . .	" .	Hydrographic Office pattern.
56 . . .	" .	" " "
76 . . .	Pastorelli .	" " "
73 . . .	" .	" " "
Thomson . . .	Casella .	Encased (Sir William Thomson's design).

SECOND SERIES OF EXPERIMENTS. Errors at different pressures. (Abridged from original.)

Thermometer.	No. 1. 250 fms.	No. 2. 500 fms.	No. 3. 750 fms.	No. 4. 1,000 fms.	No. 5. 1,250 fms.	No. 6. 1,500 fms.	No. 7. 1,750 fms.	No. 8. 2,000 fms.	No. 9. 2,250 fms.	No. 10. 2,500 fms.

EXPERIMENTS FOR CALORIFIC EFFECT.

The Phillip's encased maximum thermometers (Thomson's) being entirely protected from any effect by compression, it was decided to ascertain by their means the calorific effect produced by the sudden compression of the water in the cylinder; but, as in the two series of experiments recorded, there was such a gradual increase in the temperature of the air and also in the water used for

supplying the cylinder, that for any delicate observation the conditions were not favourable; the observations for calorific effect were therefore delayed until the weather got colder, when a more equable temperature could be ensured throughout the experiment.

In order to ascertain what time it would require for these instruments to take up temperature (as it was of importance they should not be kept under pressure longer than necessary) observations were made for the purpose, and it was found that five minutes would be sufficient time for the Thomson thermometers to take up the most minute portion of heat observable.

November 12.—The following observations were made day cloudy, all the conditions favourable.

No. 1. Pressure = 2,500 fathoms = 6,817 lbs. Under ten minutes.

Thermometer.	Diff.	Remarks.
11,424	+ 0'1	Temperature in air . . 40'0
9,649	+ 0'4	" tub . . 41'6
9,645	+ 0'2	" cistern. 38'8
		" cylinder 38'0

EXPERIMENT No. 2 (same pressure). Under pressure twenty minutes.

Thermometer.	Diff.	Remarks.
11,424	+ 0'0	Temperature in air . . 43'6
9,649	+ 0'0	" tub . . 41'2
9,645	+ 0'2	" cistern. 41'2
		" cylinder 38'9

DEEP-SEA THERMOMETER USED BY THE HYDROGRAPHIC OFFICE

It will be observed that the water pumped into the cylinder was a little warmer than that in the cylinder; but as the valve through which it passed into the cylinder is near the top, while the bulbs of the thermometers were at the bottom, the small difference it could have made in the upper water could not have affected them.

BY MR. CASELLA (previously observed).

Thermometer.	Pressure.	Diff.	Remarks.
	fms.		
	500	+ 0.2	
	1,000	0.0	
	1,500	0.0	
	2,000	+ 0.2	
	2,000	+ 0.6	
	2,000	+ 0.3	

The result of the foregoing Experiments (some rejected in forming the mean) :—

0.0178, calorific effect for each 250 fathoms' pressure.
 0.18 " " 2,500 " "

It would seem almost unnecessary, for the purpose for which this paper is prepared, to record the above observations at all, so small is the result; but as the amount of heat caused by compression is supposed by some to be much greater, it has been thought best to give it.

EXPERIMENTS TO DETERMINE THE AMOUNT OF HEAT PRODUCED BY FRICTION.

To ascertain if any error could arise from heat created by friction in a thermometer passing rapidly through the water, one of Casella's Hydrographic Office pattern was towed astern of one of the fast river-steamers (*Naiad*), keeping the thermometer well submerged by means of a

lead weight attached to the line before it; and with repeated trials at full speed not the slightest difference could be detected.

The error of the Miller-pattern thermometer as deduced from the observations (some rejected in forming the mean), *abridged* :—

Error per 250 fathoms as shown by hydraulic press 0°161 mean
Deduct for calorific effect 0°18

True error for 250 fathoms 0°143

True error for 2,500 fathoms 1°43

Mean Errors of Hydrographic Office pattern Thermometers, by testing-apparatus, corrected for calorific effect :

Fathoms.	CASELLA.	PASTORELLI.
250	1°307	1°482
500	2°789	2°654
750	3°821	4°779
1,000	4°853	5°195
1,250	5°860	6°713
1,500	7°302	7°625
1,750	8°199	9°307
2,000	9°618	10°105
2,250	10°538	11°430
2,500	12°270	12°500

The Progressive Rate of Error of the Hydrographic Office pattern Thermometers, as deduced from the foregoing table, by testing-apparatus, is by Casella, equal to an increase of effect at the rate of 0°014 per 250 fathoms' pressure; and by Pastorelli, equal to a decrease of effect at the rate of 0°044 per 250 fathoms' pressure.

Thus, while one set of thermometers show an increase of effect under pressure, the other set denote a decrease, and the mean of the two would be so small a decrease as not to be appreciable; and the practical conclusion is, that, by the testing-apparatus, the elasticity of the glass is in exact proportion to the pressure applied.

OCEAN OBSERVATIONS BY STAFF-COMMANDER E. K. CALVER

Although from the result of the experiments with the testing apparatus, a scale could be formed for the correction of the Hydrographic Office pattern thermometers, that scale may be said to be made under theoretical conditions rather than practical, and as it was necessary to verify its correctness by observations in the ocean, a number of the instruments used in the press were sent on board the *Porcupine* in 1869, and a series of most carefully taken observations were recorded by Staff-Commander Calver at the same depths as the calculated pressure applied in the press.

It is unnecessary to give the details of these observations; it will suffice to give the progressive error derived from the mean of them, and corrected for the error of the standard.

Fathoms.	CASELLA.	PASTORELLI.
250	1°329	1°210
500	2°816	2°956
750	4°002	4°779
1,000	5°127	6°482
1,250	6°286	7°065
1,500	7°00	8°118
1,750	7°301	8°301
2,000	7°711	8°844

The progressive rate of error derived from the above is by Casella, equal to a decrease at the rate of 0°13 per 250 fathoms, and by Pastorelli, equal to a decrease of effect at the rate of 0°09 per 250 fathoms.

This result, contrary to that by the hydraulic press, proves that the elasticity is not regular or in ratio to the

pressure, but that after continuing regular up to a pressure of 1,000 fathoms, it decreases in a compound ratio to a pressure of 2,000 fathoms, when its elasticity nearly ceases.

Comparison of the Hydrographic Office pattern Thermometers as found by the hydraulic testing-apparatus and by the Ocean Observations :—

Pressure.	Error.		Per 250 fathoms.	
			Press.	Ocean.
	Press.	Ocean.	Press.	Ocean.
fms.				
250	1°307	1°329	1°307	1°329
500	2°789	2°816	1°394	1°408
750	3°821	4°002	1°574	1°534
1,000	4°853	5°127	1°513	1°557
1,250	5°860	6°286	1°172	1°257
1,500	7°302	7°058	1°232	1°176
1,750	8°199	7°301	1°171	1°043
2,000	9°618	7°711	1°205	0°954
2,250	10°838	...	1°504	...
2,500	12°270	...	1°227	...
Means	...	...	1°240	1°233
Error at 2,500 fathoms by the means	...	...	12°4	12°3

Pressure.	Error.		Per 250 fathoms	
			Press.	Ocean.
	Press.	Ocean.	Press.	Ocean.
fms.				
250	1°482	1°210	1°482	1°210
500	2°654	2°956	1°332	1°493
750	4°279	4°779	1°406	1°593
1,000	5°195	6°422	1°299	1°606
1,250	6°743	7°065	1°349	1°413
1,500	7°625	8°118	1°271	1°383
1,750	9°307	8°303	1°329	1°186
2,000	10°105	8°844	1°263	1°105
2,250	11°438	...	1°271	...
2,500	12°500	...	1°252	...
Means	...	...	1°327	1°370
Error at 2,500 Fathoms by the means	...	...	13°3	13°7

By this comparison, although the errors, as found by the two modes of observation, differ at individual depths or pressure, still the means of Casella's per 250 fathoms are almost the same, and those of Pastorelli's differ only three-tenths of a degree in 2,000 fathoms, the extent to which the comparison can be made.

There can be little doubt that, without the aid of the Miller pattern, by an extended series of observations a scale could have been obtained to correct the Hydrographic Office pattern to a very close approximation of the truth (in accordance with the proposed first intention of the experiments); but the timely suggestion of Dr. Miller has quite set at rest any difference of opinion as to the instrument for future use.

OYSTERS IN IRELAND*

HIS Excellency the Lord Lieutenant of Ireland having had represented to him that the artificial propagation of oysters was imperfectly understood in Ireland, appointed in October 1868 Messrs. Blake, M.P., Francis, Hart, and Brady, commissioners to inquire into and report on the artificial cultivation and propagation of oysters.

The instructions to the Commission were to visit the principal places in France, England, and Ireland, where oyster cultivation is or can be carried on, to examine the best authorities on the subject, and to ascertain as far as possible the causes which have led to failures. It was also hinted that three weeks would suffice for Ireland, a

* Report of the Commission appointed to inquire into the Methods of Oyster Culture in the United Kingdom and France, with a View to the Introduction of improved Methods of Cultivation of Oysters into Ireland. (Presented to both Houses of Parliament by command of Her Majesty.) Dublin, 1870.

fortnight for England, and the same amount of time for France. The Commission proceeded in October 1868 to France to commence their fortnight's tour, and in June 1870 presented their report, which has now been laid before Parliament. The Report occupies about fifty pages; and 150 more are very usefully taken up with a series of appendices. Ten plates are also included in the volume.

The Report commences with a list of the places visited by the Commission, from which we notice the omission of Du'lin Bay, although Howth and Malahide had each at one time a respectable name for oysters. It then proceeds to give the natural history of the oyster, which we pass over without further comment than that it is a pity the Commissioners did not consult some person tolerably skilled in malacology ere they printed it—to criticise it would be but to break a butterfly on a wheel. The various branches of oyster fisheries are well described, and an interesting epitome is given of Coste's labours. It would appear that the great bulk of the oysters bred at Arcachon are sent to Marennes and Tremblade, where the green tint, so much esteemed in France, is imparted to the beard of the oyster. Such a prejudice exists in England against this green tint, that the Essex oysters are largely exported to France. It should be recollected that oysters impregnated with copper have always a greenish tinge of body, while those with green beards do not owe their colour to copper but to their peculiar feeding. The reporters suggest that the Diatomaceæ are probably the cause, and give figures of some Diatoms, to which we would call the attention of Dr. Donkin, who is writing a monograph of this group; to say the least, they are very comical.

The diminution in oyster production which has taken place in England, though very considerable, is not so great as in France. The Hayling Island enclosure is described, and plans of the beds given. The various methods of oyster culture are described, and appropriate places for their cultivation are pointed out. In reference to this portion of the subject, we may refer to the elaborate report on the temperature of the surface of the sea on the coasts of Great Britain, Ireland, and France, by Prof. Hennessy, in which he deduces that:

"1. The temperature of the sea on the coast of Ireland varies within narrower limits than on the coast of Great Britain, or, in other words, it is more equable throughout the year and also during the summer season, when oyster breeding takes place.

"2. The temperature of the sea at noon on the Irish coast, especially on the south and west coasts during the months of June and July, is, upon the whole, higher than on the coast of Great Britain, and less than on the west coast of France.

"3. This temperature seems to be sufficient for the requirements of oyster breeding, and therefore, *a fortiori*, the temperature about two in the afternoon under the conditions above referred to.

"4. The highest temperature of the seas surrounding Ireland, and probably also of those surrounding Great Britain, is during the month of August, and the least during the month of February.

"5. Any advantages as to temperature possessed by the seas which wash the Irish coast are unquestionably due to the thermal influence of currents connected with the Gulf Stream."

Prof. Sullivan also appends an important Report on the Composition of the Soils of Oyster Grounds, and on the qualities which exert most influence on oyster cultivation, and comes to the conclusions:—

"1. That the influence of the soil upon the breeding and growth of oysters is complicated by: temperature, especially during the spawning season; sudden alternations of heat and cold, due to currents; alternation of depth of water, especially as regards whether the maximum of sun-heat and

light concords with low water during the spawning season; velocity of tide, angle of inclination of shore, &c.

"2. That the soil of oyster grounds may be made up of materials of any of the great classes of rocks, arenaceous, argillaceous, or calcareous, provided they contain—

"3. More or less of a fine flocculent highly hydrated silt, rich in organic matter, which indicates that Diatomaceæ, Rhizopoda, Infusoria, and other minute creatures abound.

"4. That the character and abundance of such small organisms in a locality seems to be the true test of a successful oyster ground.

"5. And lastly, that although oysters do undoubtedly assimilate copper from water where mine-water containing traces of that metal flows into the sea in the neighbourhood of the oyster beds, the copper is chiefly, if not exclusively, confined to the body of the oyster, and does not appear to reach the mantle or beard. That the so-called green oysters of Essex, Marennes, and other places, on the other hand, are green-bearded and contain no copper, nor can the most minute trace of copper be detected in the soil of the oyster grounds where such green-bearded oysters are produced."

The Report concludes with the following recommendations:—

"1. That all regulations with regard to the close time around the Irish coast should be strictly maintained.

"2. That the inspectors of Irish fisheries should have power, whenever they determine to reserve a bank or any portion thereof from public dredging for the purpose of recovery, to make such arrangements as may seem desirable for keeping the restricted part free from weeds and vermin.

"3. That there should be procurable at each coastguard station, at a small cost, general information as to oyster culture, and simple instructions as to the best modes of proceeding.

"4. That the inspectors be empowered to adopt such other means as they may deem necessary to afford information and instruction to those requiring it with respect to oyster culture.

"5. That having unsizable oysters in possession in places where it is prohibited by any bye-law to take oysters from any public beds under a certain size, shall be *prima facie* evidence that such oysters were taken in places so prohibited; such regulations not to apply to private oyster grounds.

"6. That facilities be afforded to the coast population to acquire the use of small portions of foreshore, or sea bottom, for oyster cultivation, and to obtain loans on satisfactory security for the preparation of same, and for the purchase of oysters, collectors, &c.

"7. That landed proprietors desirous of cultivating oysters on the shores adjoining their lands, be empowered to avail themselves of the provisions of the Irish Land Improvement Acts, for the purpose of oyster cultivation."

We would commend the perusal of this Report to those interested in this subject; of its importance there can be little doubt; and while we agree with the commissioners that no very extraordinary profits are to be made out of oyster culture, and that hence it is not a subject for extensive commercial speculation, yet we know of none more deserving of the attention of those interested in the general welfare of this country. E. P. W.

ARTIFICIAL MILK

AMONG the many sorrowful records of the Siege of Paris, one of the most enduring, and not the least touching in its melancholy eloquence, is afforded by the

Comptes Rendus of the Academy of Science. The construction, the filling, the guiding, and general management of balloons, occupied so much of the attention of the Academy, that, if all other records of the Siege were lost, its date and effective duration might be pretty accurately determined by the sudden appearance, the continuance, and sudden cessation of these abundant papers on aërostation.

There is another series of papers of equal, if not greater significance, viz., those on the utilisation of strange materials for food, the economising of waste nutritive materials, and their substitutive uses.

The investigations on these subjects have led to more practical results than the papers on aërostation. This has been especially the case with the researches that are described in the papers of M. Boillott, M. Dabrunfant, and M. Charles Fua, on "Alimentary Fats."

"Alimentary fats" is a wide expression, including some rather unsavoury hydro-carbons and very curious refuse materials. The main object of these investigations was to determine how such substances may be "usefully employed in alimentation," or, in plain unsophisticated English, how to make butter from candle-ends, dirty dripping, colza oil, fish oils, the refuse of slaughter houses, the restored grease of the wool-dresser, &c. The general result has proved that the "frying process"—which was not altogether unknown to certain enterprising Englishmen before the investment of Paris—is triumphant over all its rivals; that by simply raising the fat to 140° or 150° Centigrade, and in the mean time cautiously sprinkling with water, the cellular tissue, the volatile oils, the rancidity, offensive odours, and all other non-sentimental impediments to "alimentation," are removable.

This frying process has already effected something like a revolution in the industry of soap-boilers, some of whom have changed their trade to that of butter-fryers. We may thus explain the remarkable fact that, although the excessively dry summer of 1870 reduced the dairy produce of England to about half the average, and had nearly the same effect on our other sources of cow-butter supply, there was no material reduction in the supply or consumption of fresh butter for the London and Provincial markets during the following winter, the only notable disturbance which occurred being in the demand for kitchen-stuff and empty Dutch butter-tubs.

M. Dabrunfant is not content with superseding the cow in the matter of butter, but has subsequently made similar attempts upon milk. He proceeds in a strictly scientific manner, commencing with the following summary of the results of Boussingault's analysis of cow's milk:—

Nitrogenous material (caseine and albumen)	0.0337
Fatty material (butter)	0.0376
Sugar (of milk)	0.0567
Salts	0.0020
Water	0.8700

Quoting the observations of Payen and others which show that milk is alkaline, and owes its alkalinity to soda, he proceeds to refute the theory of churning which has been generally adopted by microscopists, viz. that the fat globules in milk are invested with a delicate membrane which is ruptured in the churn, and thereby permits the agglomeration of the fatty material into butter.

M. Dabrunfant contends that milk is simply an emulsion of neutral fatty matter in a slightly alkaline liquid, such as can be artificially imitated; and that the process of churning consists in hastening the lactic fermentation, thereby acidifying the serum of the milk, and at the same time agglomerating the fatty matter which the acidity sets free from its emulsion. He further controverts the cellular theory by showing that the fat globules of milk do not display any double refraction, as do all organised membranous tissues.

Having thus examined the theoretical constitution of milk, he proceeds to the practical method of imitating it,

and gives the following directions: Add to half a litre of water forty or fifty grammes of saccharine material (cane sugar, glucose, or sugar of milk), twenty or thirty grammes of dry albumen (made from white of egg), and one or two grammes of subcarbonate of soda. These are to be agitated with fifty or sixty grammes of olive oil or other comestible fatty matter until they form an emulsion. This may be done either with warm or cold water, but the temperature of 50° to 60° C. is recommended. The result is a pasty liquid, which, by further admixture with its own bulk of water, assumes the consistency and general appearance of milk.

Luxuriously-minded people who prefer rich cream to ordinary milk can obtain it by doubling the quantity of fatty matter, and substituting two or three grammes of gelatine for the dry albumen. The researches of Dumas and Fremy having reinstated gelatine among the nitrogenous alimentary materials, M. Dabrunfant prefers gelatine to albumen; it is cheaper, more easily obtained, and the slight viscosity which it gives to the liquid materially assists the formation and maintenance of the emulsion. He especially recommends this in the manufacture of "siege-milk," on account of the obviously numerous articles from which gelatine may be obtained.

The uses of artificial milk need not be limited to supplying the wants of the residents of besieged cities. As an ordinary element of the human breakfast table, it is not likely to supersede the product of the cow, but calves are suggested as being superior to vulgar human prejudices. In the ordinary course of rearing, these animals demand a large proportion of the milk of their mothers, and are commonly ill-fed or prematurely sacrificed on that account. By feeding them luxuriously on artificial milk (which may be still further cheapened by using colza oil, which has been rendered tasteless and alimentary by the frying process above described), the milk, butter, and cheese of the cow may be considerably economised, and the supply of veal improved both in quantity and quality, by keeping the calves a much longer time before they are killed.

I might make further suggestions in the direction of "dairy-fed pork," &c., but this is unnecessary, the commercial instinct is sufficiently strong to avail itself of all such cheapening applications of science. Those who are professionally engaged in detecting the adulterations of food will do well to study the physical peculiarities by which M. Dabrunfant's milk may be distinguished from that of the cow, both in the ordinary and condensed form. By substituting vegetable albumen for the white of egg or gelatine, the vegetarian may prepare for himself a milk that will satisfy his uttermost aspirations.

W. MATTIEU WILLIAMS

NOTES

The following telegrams have been received from the Eclipse Expedition since our last:—"MANGLORE, Wednesday, Dec. 6.—We have landed here from the flagship; all well. The Government arrangements are admirable. The weather is promising. The parties are posted as arranged." From N. R. Pogson, at Avenashy, to the Astronomer Royal, Royal Observatory, Greenwich:—"Weather fine; telescopic and camera photographs successful; ditto polarisation; good sketches; many bright lines in spectrum.—Dec. 12." From Colonel Tennant, F.R.S., Dodabeta, Ootacamund, to W. Huggins, F.R.S., Dec. 12, 9.15 A.M.:—"Thin mist. Spectroscope satisfactory. Reversion of lines entirely confirmed. Six good photographs."

At the meeting of the Geological Society on the 6th inst., the President announced the bequest to the Society, on the part of the late Sir R. I. Murchison, of the sum of 1,000*l.*, to be invested in the name of the Society or its trustees, under the title of the "Murchison Geological Fund," and its proceeds to be annually devoted by the Council to the encouragement or assis-

tance of geological investigation. The donation of the proceeds of the fund was directed by the testator to be accompanied by a bronze copy of the Murchison Medal.

At the meeting of the Royal Geographical Society on Monday last, Sir Henry Rawlinson stated that the Council intended to address the Foreign Office, with a view of arranging, either directly from the Foreign Office, or through co-operation between the Foreign Office and the Society, some means of communicating with Dr. Livingstone, either by sending messengers into the interior of Africa, and offering a reward of 100 guineas to any African who will bring back a letter in Dr. Livingstone's handwriting to the sea-coast, or by organising a direct expedition, headed by some experienced and well-qualified European, who should himself penetrate to the point where Dr. Livingstone is supposed to be.

By a decree, dated April 18, 1866, of the Minister of Public Instruction in France, a prize of 50,000fr. (2,000l.) was offered for the most useful application of the Voltaic Pile, the period for competition to expire in April 1871. From a report of the minutes presented by the President of the Republic, it appears that candidates are few in number, and that in the opinion of the *savants* to whom the memoirs were submitted, none is of sufficient merit to have earned the prize. By a decree of the 29th of November, the competition is now extended for another period of five years, to terminate on November 29, 1876.

We learn from the *Lancet* that the promoters of the scheme for commemorating the life and labours of John Goodsir, late Professor of Anatomy in the University of Edinburgh, have got only 700l. instead of 2,000l., and have had to relinquish the idea of a fellowship, and adopt that of a triennial prize, to be open to all graduates of the University of not more than three years' standing, to be given for an essay or treatise containing the results of original investigations in anatomy, human and comparative, either normal or pathological, or in experimental physiology. The Acting Committee of the Association for the better Endowment of the University of Edinburgh have prepared the deed of endowment for the Syme Memorial. The capital sum amounts to 2,500l.; whereof 2,000l. were paid over to the Association by the Syme Memorial Committee, and 500l. was added by the Association.

The authorities of the Museum of Comparative Zoology at Harvard College have placed in Prof. Allman's hands for determination the whole of the collection of hydroid zoophytes obtained by the United States Coast Survey during its late exploration of the Gulf Stream.

The Council of the University of Edinburgh has decided to take into consideration on the 21st inst. the appeal against the decision of the Senate as to rescinding the regulations for the education of women in medicine.

The Examiners in the Natural Science School at Oxford (W. Ogle, M.D., Corpus; J. A. Dale, Balliol; and R. H. M. Bosanquet, St. John's) on Saturday issued the subjoined class list:—Class I.—H. A. Black, Christ Church; W. T. Gooden, Magdalen; E. H. Jacob, Corpus; A. S. L. Macdonald, Merton; J. A. Ormerod, Jesus; A. G. Rücker, Brasenose; S. H. West, Christ Church. Class II.—E. H. Forty, Christ Church; J. Turner, Exeter; J. L. Twynan, St. Mary Hall. Class III.—*Nil*. Class IV.—*Nil*.

MR. W. A. BRAILEY, who was second in the Natural Sciences Tripos at Cambridge, has been elected a Fellow of Downing College in that University.

M. GEORGES DELAPORTE, engineer of M. Tessié de Motay's Oxy-hydrogen Light Company, has been nominated a Chevalier

of the Legion of Honour, as an acknowledgment of the services rendered to the State during the Siege of Paris in the application of the Electric Light to strategic operations.

THE Lord President of the Council has nominated Mr. T. S. Aldis, formerly scholar of Trinity College, Cambridge (Second Wrangler in 1866), to be an Inspector of Schools.

The following are now announced as the probable arrangements for the Friday evening meetings at the Royal Institution before Easter 1872:—January 19, Mr. William R. Grove, F.R.S., on Continuity; January 26, the Archbishop of Westminster, on the Demon of Socrates; February 2, Prof. Odling, F.R.S., on the new metal Indium; February 9, Prof. Humphry, F.R.S., on Sleep; February 16, Dr. Gladstone, F.R.S., on the Crystallisation of Silver and other Metals; February 23, Mr. Henry Leslie, on the Social Influence of Music; March 1, Mr. C. W. Siemens, F.R.S., on Measuring Temperatures by Electricity; March 8, Mr. R. Liebreich, on the Effect of certain Faults of Vision on Painting, with especial reference to Turner and Mulready; March 15, Mr. John Evans, F.R.S., on the Alphabet and its Origin; March 22, Prof. Tyndall, F.R.S.

We learn from *Les Mondes* that the lamentable disagreement between M. Daubrée, the director of the mineralogical department of the Museum of Natural History at Paris, and his assistant, M. Stanislas Meunier, is now happily terminated, and that the latter is again permitted to carry on his researches at the Museum.

THE Exhibition of the Photographic Society, held in its rooms in Conduit Street, closed on Saturday last. While among specimens of portraits the works of Grasshoff of Berlin, Rylander of Paris, and other Continental artists, challenged comparison with any of our home productions, there can be no question that in landscape photography, the exquisite workmanship of Bedford, Robinson, Cherrill, and some other English photographers, easily bore off the palm. There were some very fine specimens of Edwards's heliotype process, as well as of the autotype and other carbon-printing processes.

We learn from the *American Naturalist* that the State Microscopical Society of Illinois has issued a prospectus of *The Lens*, a Quarterly Journal of Microscopy and the Allied Natural Sciences; with the Transactions of the State Microscopical Society of Illinois. It will be an octavo, each number containing at least forty-eight pages of reading matter. Terms, 2 dols. per annum in advance. The editor will be Mr. S. A. Briggs, 177, Calumet Avenue, Chicago. Though its appearance has been delayed by the fire, we learn that it will soon be issued.

At a recent meeting of the Asiatic Society of Bengal Mr. W. T. Blanford exhibited a collection of chipped quartzite implements found about forty miles west of Bhadrachalam, on the Godavari. The thirty-five specimens exhibited were all found within a space of about fifty yards square, and at least as many more were rejected on account of being badly made. The place where they were found was in dense jungle, the rock soft sandstone, and the implements, as was usually the case in Southern India, had evidently been chipped from pebbles. Several were formed of white vein quartz, an unusual circumstance. The forms of these implements were those of the kind most frequently found in French and English gravels, and they varied from about 3in. to 6in. in length. That the spot where they were found was a place of manufacture was probable, not only from the occurrence of ill-formed implements, but also from flakes, evidently chipped from the quartzite being abundant.

A VERY beautiful and extraordinary *Aurora Borealis* was witnessed at Montreal on November 21. The following account of

the phenomenon has been sent us by Dr. Smallwood of the Montreal Observatory:—A few minutes past 5 o'clock yesterday evening, the eastern horizon showed a bank of cumulo-stratus clouds, which reached to an altitude of 9° , behind which was discernible an auroral light, which increased in intensity as the darkness became more dense. At 5.30 a diffused light of a bright crimson colour occupied the whole of the eastern and north-eastern horizons. Rising behind this bank of clouds, streamers were frequently observed, reaching to the constellation Cassiopeia. The light was frequently so dense as to prevent even the stars δ and γ Ursæ Majoris being seen through it. While these appearances were present, a far more brilliant display was seen in the north-west, triangular in shape, its base hidden by the Mountain, but which appeared about 10° in breadth, and extended upwards, passing part of the constellations Hercules, Corona Borealis, and Draco, to the zenith. The bright crimson colour was very intense; its edges were occasionally softened by a band of narrow streamers of a palish green colour. Stars below the third magnitude were hidden from view, owing to the great density of this light. Small patches of cumulus clouds were seen passing across and in front of this display. The surpassing beauty of these appearances has rarely been equalled. At 6.15 P.M. the intensity of the brightness was much diminished, and at 7 only a soft auroral light was visible in the north and north-east. The declination magnet was very sensibly deflected from its normal state, showing a great easterly variation. The weather during the day was comparatively warm (having succeeded a slight fall of snow), with a rising barometer, which at 6 P.M. stood at 29.502 inches. Thermometer, 37° . Humidity, .866. Wind west; velocity three miles per hour.

PROF. PANCERI, of Naples, has been studying for some time past the phosphorescence of marine animals. He has examined *Noctiluca*, *Beroë*, *Pyrosoma*, *Pholas*, *Chatopterus*, and has lately published a paper on the phosphorescence of *Pennatula*. He finds in all cases that the phosphorescence is due to matter cast off by the animal—it is a property of dead separated matter, not of the living tissues. In all cases (excepting *Noctiluca*) he also finds that this matter is secreted by glands, possibly special for this purpose, but more probably the phosphorescence is a secondary property of the secretion. Further, the secretion contains epithelial cells in a state of fatty degeneration, and it is these fatty cells and the fat which they give rise to which are phosphorescent. Hence the phosphorescence of marine animals is brought under the same category as the phosphorescence of decaying fish and bones. It is due to the formation in decomposition of a phosphoric hydro-carbon, or possibly of phosphuretted hydrogen itself. In *Pennatula* Prof. Panceri has made phosphorescence the means of studying a more important physiological question—namely, the rate of transmission of an irritation. For when one extremity of a *Pennatula* is irritated, a stream of phosphorescent light runs along the whole length of the polyp-colony, indicating thus by its passage the rate of the transmission of the irritation. This admits of accurate measurement, and furnishes data for extending Helmholtz's and Donder's inquiries to animals so widely separated from their "Versuchs-thiere" as the *Calentaria*. It is also a proof of the thoroughness of Prof. Panceri's investigation that he has made use of the spectroscope for studying the light of phosphorescence.

ATTENTION has been called in *Tarper's Weekly* to the injuries to the Florida submarine cable supposed to have been caused either by the bites of the sea-turtles, or from some kinds of fish; and we now learn that in China a similar difficulty has been experienced in consequence of the attacks of a minute crustacean. This is so small as scarcely to be perceptible to the naked eye, but can be readily defined under the microscope. Various breaks have been satisfactorily referred to the agency of these animals,

which had embedded themselves in the gutta percha. It has become necessary, therefore, to envelop the cables in certain localities with an external supplementary layer of metallic wire, in order to prevent injury in this manner.

WITH a commendable promptness, the first volume of the Annual Report of the United States Commissioner of Patents for 1870 has made its appearance, and inaugurates the new order in regard to this document. Instead of publishing the specifications of the patents with wood-cut illustrations, the present volume embodies—first, an alphabetical list of patentees during the year; second an alphabetical list of the patents extended during the year; next, an alphabetical list of inventions and of reissues. It will be remembered that at the present time the patents are printed in detail, accompanied by photo-lithographic drawings of working size, 150 copies being published, some of them to be distributed, and sets placed for free public inspection in the various State and Territorial capitals, and in the clerks' offices of the District Court of the various judicial districts throughout the United States. The issue of additional copies is also authorised in proportion to the demand, to be sold at a price not exceeding the contract price for such drawings. The total number of patents issued during the year 1870 amounted to 13,321, of which considerably the largest number were made out to citizens of New York, Pennsylvania, Massachusetts, Ohio, Illinois, Connecticut, Indiana, and Michigan, in the order mentioned.

THE *Mechanics' Magazine* states that amber is reported by the collectors as being sometimes found in a soft "unripe" state; Herr H. Spürgatis was fortunate enough to receive a specimen from the Baltic, near Brusterort, East Prussia. Its interior consisted of an almost transparent yellow resin, surrounded by a thin opaque crust. When freshly broken the centre was soft and elastic, but on exposure to the air it soon became hard and brittle. Its analysis differed so much from that of amber, that though it evidently belongs to the same class of substances, it is not to be mistaken for it. Its percentage composition agrees with that of Benneheim asphalt, and with the fossil resins from the East Indies, examined by Duflos and Johnston.

ON Nov. 7 at 2.30 P.M. a slight earthquake was felt at Smyrna. It was simultaneous at Mytilene and Cheshmeh.

TWO smart shocks of earthquake were felt at Cavalla in Macedonia at 11 P.M. on Nov. 28.

ON Oct. 13 an earthquake was felt in the fort of La Libertad, at 11 P.M. It was also felt at La Union and Nicaragua.

ABOUT a year ago many English and foreign scientific journals, following the *Bulletino Romano*, announced that a large meteorite had fallen near the town of Murzuk, in December 1869. M. Rose has lately made a communication to the Berlin Academy, in which he states that the results of his inquiries made both at Tripoli and Murzuk have shown that no such fall was ever observed, much less that any such meteorite had been found.

It is stated in *Land and Water* that the whole of the pack of fox-hounds of the Durham County Hunt has been condemned to be destroyed in consequence of the prevalence amongst it of a form of hydrophobia defined as "dumb madness," which has run through the kennels, and has carried off twelve couple of hounds. As to the details of this "dumb madness," it will be interesting to hear more of the exact symptoms attending it. Old works upon canine diseases used to specify seven species of canine madness, "dumb madness" among them, the last and worst being "running madness," which was undoubtedly hydrophobia, though probably many other phases of so-called madness were simply distemper, which in primitive days was little understood as a specific disease.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, September. This number opens with numerous editorial notes, principally abstracts from other scientific journals; there is also the commencement of a description of the Stevens Institute of Technology in Hoboken. Amongst the notes we notice an account of Grubb's automatic spectroscope, and a description of the properties of Nitroglycerine as found by M. Champion. It is stated that when pure it may be heated up to 200° without explosion, but at 257° it deflagrates violently; and although it explodes with terrific force by a blow, the electric spark does not affect it. A number of original communications follow. Under the head of Civil and Mechanical Engineering, we find a paper containing some useful "formulae, rules, and examples for cases of earth-work under warped and plain surfaces," and another "On Descriptions of Wood-working Machinery." Under mechanics, physics, and chemistry, there is a paper "On Apparatus Illustrating Mechanical Principles;" the various pieces of apparatus are intended to show experimentally the truth of problems, such as the parallelogram of forces, the parallelopipedon of forces, and so on; and a machine is also described to illustrate the action of the forces of gravity and projection in giving a projectile its parabolic trajectory. They are designed by J. Pemberton, and seem to be well adapted to the various purposes which have hitherto been neglected. The continuation of a lecture on the sun by Dr. Gould follows; he deals shortly with the prismatic analysis of light and with the solar spectrum, explaining the curves of thermal, luminous, and chemical intensity. Prof. Leeds contributes a valuable paper for the use of students "On the Measurement of the Angles of Crystals," and Mr. Coleman Sellers reviews Mr. Crookes's Experimental Investigation of a New Force; he boldly states that he believes Mr. Crookes has been deceived, giving several reasons why he is of this opinion. An editorial note is attached to this paper, stating that Mr. Sellers is very accomplished in the field of legerdemain, which would lend peculiar value to his view.

Journal of the Franklin Institute, October. The editorial notes contain several valuable abstracts, amongst which may be noticed one on Fluorescence, originally published by E. Lommel in the "Report, der Physik." From his observations Lommel shows that Stokes's law "that the refrangibility of the exciting rays is always the upper limit of the refrangibility of the excited rays" does not always hold good, and also that the very common opinion that Fluorescence is an action by which refrangible rays are converted into less refrangible rays is not altogether true.—Prof. Thurston communicates a report "On a Steam Boiler Explosion," to which is added a clear statement of many of the causes of such explosions. Prof. Heines contributes the first of a series of papers on binocular vision; he deals shortly with the human eye and monocular vision, and then proceeds to some phenomena of binocular vision. The last paper was read before the American Association for the advancement of Science by Prof. Owen, "On Physiographic and Dynamical Geology involving the discussion of Terrestrial Magnetism," in which it is thought probable that the sun is the source of the modifications on the earth, giving the form and dimensions to the land, and that magnetism either directly or by conversion into chemical force, has been the most powerful agent in causing various natural phenomena, such as the geysers, volcanoes, ocean currents, &c.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 7.—"On the Fossil Mammals of Australia. Part VI. Genus *Phascalomys*, Geoffr."—By Prof. Owen, F.R.S. In this paper the author premises a reference to former ones on the Osteology of existing *Marsupialia*, in the "Transactions of the Zoological Society," and to his "Catalogue of the Osteological Series in the Museum of the Royal College of Surgeons," in which are defined cranial characters serving to distinguish existing species of the genus *Phascalomys*, Geoffr.; and after showing, in subsequently received materials, the kind and extent of variety of such characters in the same species, he proceeds to apply the knowledge so gained to the determination of some fossil remains of species of Wombat, similar in size to the known existing kinds. The extinct *Phascalomys Mitchellii*, indicated by remains brought to England in 1835 by Sir Thomas Mitchell, C.B., the

discoverer of the bone-caves of Wellington Valley, Australia, is determined by specimens subsequently obtained by Prof. Alex. M. Thomson and Mr. Gerard Krefft, from the same caves. A second species, distinguished by characters of the nasal bones, is called after its discoverer *Phascalomys Krefftii*. Modifications of the lachrymal, maxillary, and palatal bones in the existing kinds of Wombat are also applied to the determination of the fossils: specimens from the fresh water deposits of Queensland are thus shown to belong to the species *Phascalomys Mitchellii*, originally founded on fossils from the breccia-caves of New South Wales. The author next proceeds to point out the characters of the mandible in existing Wombats, available in the determination of extinct species of *Phascalomys*. On this basis he defines specimens which he provisionally refers to his *Phascalomys Krefftii*. He then points out the mandibular characters of *Phascalomys Mitchellii*, and shows that the existing *Phascalomys latifrons* was represented by mandibular fossils from the breccia-caves of Wellington Valley. Proceeding next to the description of fossil mandibular remains of the genus *Phascalomys* from the fresh water deposits of Queensland, the author defines *Phascalomys Thomsoni*, *Phasc. platyrhinus*, and *Phasc. parvus*. The latter, seemingly extinct, species is markedly inferior in size to any of the known existing species. An account of the extinct kinds of Wombat, exceeding in size the existing species, will be the subject of a succeeding communication. The present is illustrated by subjects occupying seven plates and eight woodcuts, all the figures being from nature, and of the natural size.

"On Fluoride of Silver. Part III." By G. Gore, F.R.S.

"On the Solvent Power of Liquid Cyanogen." By G. Gore, F.R.S.

Zoological Society, December 5.—John Gould, F.R.S., V.P., in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of October and November 1871, and called particular attention to a young female specimen of the Cape Fur-Seat (*Otaria pusilla*), presented by Sir Henry Barkly, Governor of the Cape Colony, being the first example of this interesting animal received alive in Europe.—A letter was read from Dr. Burmeister, of Buenos Ayres, containing remarks on Messrs. Slater and Salvin's "Synopsis of the Cracidae," published in the Society's "Proceedings" for 1870.—Dr. E. Hamilton exhibited and made some remarks on an adult skull of the newly-discovered Chinese Deer (*Hydropotes inermis*), and compared it with an immature skull of the same species exhibited by Mr. R. Swinhoe at a meeting of the Society, February 10, 1870. Dr. Hamilton also drew attention to the statement made by his correspondent respecting the wonderful fecundity of this animal, which tended to corroborate the facts stated by Mr. Swinhoe on that occasion.—Mr. Slater exhibited and remarked on a skin of the Water Opossum (*Chironectes variegatus*), which had been sent to him by Mr. Robert B. White, from Medellin, United States of Columbia.—Prof. Newton exhibited and made remarks on the humerus of a Pelican (believed to be *Pelecanus crispus*), which had been found in the English fens.—A communication was read from Surgeon Francis Day, Inspector-General of Fisheries of British India, containing remarks on the freshwater Silurids of India and Burmah, with observations on the range of the species, their classification, and general geographical distribution.—Mr. A. G. Butler read a paper on a small collection of Butterflies made at Loanda, the capital of the Portuguese Settlements of Angola. A second paper by Mr. Butler gave the description of a new genus of Lepidoptera, allied to *Apatura*, which was proposed to be called *Eulaccira*.—A paper by Mr. E. A. Smith was read, containing a list of species of Shells from the Slave Coast, West Africa, collected by the late Commander Knocker, R.N., the majority of which had been dredged at Whydah, on the Dahomey shore.—Prof. Newton communicated some notes by Herr Robert Collett, of Christiana, on the singular asymmetry of the skull in Tengmalm's Owl (*Strix tengmalmi*).—Mr. Slater read the third and final portion of a series of notes on rare or little-known animals now or lately living in the Society's Gardens. Mr. Slater gave an account of a collection of Birds from Oyapok, on the river of the same name which divides Cayenne from the northern frontier of Brazil, amongst which were two species believed to be undescribed, and proposed to be called *Ochthoeca murina* and *Heteropelma igniceps*. A third communication from Mr. Slater contained remarks on the species of the genera *Myiozetetes* and *Conopias*, belonging to the family Tyrannidae.—Mr. E. W. H. Holdsworth read some notes on the Red-spotted Cat (*Felis rubiginosa*) of

Ceylon, and its varieties. — Mr. D. G. Elliot read a paper on various Felidae, rectifying the synonymy of several species, and giving a more perfect description of one recently obtained from North-West Siberia, which he proposed to call *Felis capitulata*. Dr. Günther made a reply to some critical remarks in a paper by Surgeon Francis Day, read at a recent meeting of the Society.

Geologists' Association, December 1. — The Rev. Thomas Wiltshire, M.A., F.G.S., president, in the chair. — "On the Glacial Drifts of North London," by Mr. Henry Walker. These drifts were described under the classification and nomenclature given to the glacial deposits by Mr. Searles V. Wood, jun. They were traced from East End (Ilighgate) and Muswell Hill to Finchley, Colney Hatch Lane, and Whetstone. The profusion of chalk found in the glacial clay at these places bears out the designation of the main deposit in south-eastern England as the great Chalk Boulder Clay; but it is also found that the sands and gravels of the Middle Glacial, which Mr. Wood seems to restrict to a much lower horizon than Finchley, are also to be found at these localities. At Whetstone the Chalky Boulder Clay is found overlying twenty-five feet of gravel and sand, and in the apparently corresponding beds at Finchley and Hendon Lane, drift fossils and casts are occasionally found. Mr. Henry Hicks agreed with the conclusion that these sands and gravels are Mr. Wood's Middle Glacial. Mr. Caleb Evans thought that the heights to the north of London marked the southern termination of the glacial drift. Mr. Batt considered that the Drift had extended to the country south of the Thames. Several other gentlemen took part in a very animated discussion. — Collections of fossils and boulders from the Middlesex Drift were exhibited, and a quantity of peat obtained from the same source, was shown by Mr. J. T. B. Ives.

Society of Biblical Archaeology, December 5. — Prof. Donaldson, D.D., F.R.S., in the chair. A paper by the Chevalier de Saulsy, membre de l'Institut, "On the true sites of Capernaum, Chorazin, and Bethsaida (Julias)" was read by the secretary. In the chevron's paper, which took the form of a letter addressed to the Dean of Westminster, he stated that, having considered the whole tenor of the argument first advanced by him in the *Revue Archéologique* twenty years ago, he could come to no other conclusion than that the traditional town of Bethsaida and the identification of Kharasch as Chorazin and Tel Houm as Capernaum were unsupported by geographical evidence, and were contrary to the express statements of Josephus, who would be sufficiently exact in describing the town where he was wounded. At the same time the ruins of Kharasch were too extensive to be those of insignificant village like Chorazin; and those of supposititious B. thasaida were too few, and contained no indications of the Family Mausoleum of Herod Philip. The conclusion of the author was that Tel Houm was more probably the real site of Capernaum. A considerable amount of philological evidence illustrated these statements. On the close of the reading of this paper an interesting discussion ensued, in which the chairman and the following gentlemen took part: — Mr. W. R. A. Boyle, Dr. Cull, Mr. S. M. Drach, Mr. John Macgregor, and Captain Wilson.

Entomological Society, December 4. — A. R. Wallace, president, in the chair. — Mr. Shearwood exhibited an extraordinary variety of *Argynnis aglaia*, taken at Teignmouth. Mr. Bond exhibited varieties, or malformations, of various British *Lepidoptera*. — Mr. Jan on exhibited a large collection of insects (chiefly *Coleoptera*) from the diamond fields of South Africa. — Mr. Higgins exhibited examples of *Tetracha crucigera* of MacLeay, from Australia. — Prof. Westwood made some remarks concerning *Papilio Thersander*, figured by Donovan, and arrived at the conclusion that this species (figured originally by Jones in his "Icones") was founded on the combination of a *Papilio* with *Charaxes fabius*. A discussion ensued concerning the right of named figures of insects, by the older authors, to be regarded in questions of priority. — With reference to the question of the liability of large dragon-flies to the attacks of birds, Mr. Müller called attention to a statement by Natterer, to the effect that some species of *Falco* habitually prey upon dragon-flies. Mr. Horne stated that during his residence in India he had never seen those insects attacked by birds of any description. — Major Parry communicated notes concerning *Lisoporus Hewittianus*, and Mr. W. F. Kirby on the synonymy of various *Lepidoptera*.

Linnean Society, December 7. — Mr. G. Bentham, president, in the chair. "On the formation of British Pearls and their

possible improvement," by R. Garner. The author referred to the theory, now generally adopted, that the production of pearls in oysters and other mollusks is caused by the irritation produced by the attacks of the minute parasite known as *Distoma*, and believed that, by artificial means, this parasite might be greatly increased. British pearls are obtained mostly from species of *Unio*, *Anodon*, and *Mytilus*, but it is probable that all mollusks, whether bivalve or univalve, with a nacreous lining to the shell, might be made to produce pearls. An interesting discussion followed, in which Mr. Gwyn Jeffreys, Mr. Holdsworth, and Dr. Murie took part. — "On certain Coleopterous Larvæ," by Dr. Burneister, of Buenos Ayres. — "On the Botany of the Speke and Grant expedition," by Lieutenant-Colonel Grant. Notwithstanding the difficulties of their journey, and that they had more than once to destroy or abandon their whole collection, Captain Speke and Captain Grant succeeded in bringing home between 700 and 800 species of plants, many of them entirely new, which have been described by Prof. Oliver, and will be published in the "Transactions" of the Society, with at least 100 plates.

Anthropological Institute, December 4. — Sir John Lubbock, Bart., president, in the chair. — Messrs. J. Cordy Burrows, J. Park Harrison, and P. C. Sutherland were elected members. Captain Richard F. Burton read his second paper on "Anthropological Collections from the Holy Land." The paper included a catalogue raisonné of articles presented to the museum of the institute, found by Mr. John S. Rattray at Sâhib El Zamân (Lord of the Age), the reputed tomb of Hezekiah. This "find" consisted of fragments of human skulls and long bones, old copper bracelets, brass bracelets, coins, bits of lachrymatories (the glass being highly iridescent), portions of Syrian majolica of the type of that usually made at Damascus by the Tartars, beads of various kinds, &c. The tomb was situated in a hollow on the Eastern slope of the Libanus, and proved to be an artificial cavern, with a shaft for ventilation. A full detailed description of this very interesting discovery was given. Another interesting discovery made by Captain Burton was at the upland village of Ma'alulah, distant three hours from the large convent Saidnâya, roughly speaking N.E. of Damascus, and occupying a position on the N.E. ranges of the Anti-Libanus. This find consisted of various fragments of skulls and lower jaws, which, together with the human remains from the tomb at Sâhib El Zamân, were described by Dr. Carter Blake. The third part of Captain Burton's paper was occupied by an account of a series of flint and stone implements and flakes, and articles of bronze and bone found near Bethlehem. In a detailed description of these articles Mr. John Evans, F.R.S., pointed out for special notice a basaltic hammer, which differed from the usual form of similar instruments discovered in Scandinavia, in Britain, and in North America, inasmuch as in the specimen the lateral depressions were absent. — Prof. Busk, F.R.S., read a communication from the Rev. Mr. Dale on flint implements from the Cape of Good Hope, which were exhibited on the table; and Mr. F. W. Rudler, F.G.S., exhibited a stone implement of unique form, also from the Cape. The President submitted for inspection some stone implements of rare beauty from Greece.

Quekett Microscopical Club, Nov. 24. — Prof. Lionel S. Beale in the chair. A paper was read by Mr. M. C. Cooke on "The Minute Structure of Tremelloid Uredines (*Podisma*)," in which the structure of the Tremelloid masses, commonly found on juniper bushes, was detailed, together with the results of the observations of Tulasne, Oersted, and others on the germination and development of these fungi, with the actual examination of the species described under the genera *Gymnosporangium* and *Podisma*. It was held by the author that no good foundation existed for the constitution of two genera, since the minute structure and development of both were identical. Some conversation ensued on the phenomena of alternation of generations which these and other fungi present, and especially in cases where some of the phases of existence were presumed to be passed on different hosts. Especial reference was made to the opinions entertained by Prof. Oersted that the *Podismas* were found in one state parasitic on leaves of Pomaceous trees, as *Rustelias*, &c., in another stage inhabiting the branches of junipers, as *Podisma*. The author of the paper did not consider that this supposed phenomenon was satisfactorily proved.

MANCHESTER

Manchester Literary and Philosophical Society, October 31. — E. W. Binney, F.R.S., president, in the chair. —

Mr. Wm. Boyd Dawkins, F.R.S., gave a short account of the discoveries in the Victoria Cave, made since the last account was published in the Transactions of the Society. The clay forming the bottom of the cave, and which hitherto had been barren, was now yielding broken fragments of bone, some of which had been gnawed by the cave-hyena. A lower jaw of this animal was found, which indicated the presence of the characteristic Pleistocene mammalia in a part of Yorkshire in which they had not been known to have existed up to the present time. There were, therefore, three distinct groups of remains in the cave, the Romano-Celtic on the surface, the Neolithic beneath, and lastly that which has been furnished by the clay which is glacial in character. And since two feet of talus had been accumulated above the Romano-Celtic layer during the last 1,200 years, it is very probable that the accumulation of debris of precisely the same character between the Romano-Celtic and Neolithic layers, six feet in thickness, was formed in about thrice the time, or 3,600 years. If this rough estimate be accepted, and it is probably true approximately, the Neolithic occupation of the cave must date back to between 4,000 and 5,000 years ago. There is no clue to the relative antiquity of the group of remains found in the clay; but it may safely be stated to be far greater than that of the Neolithic stratum. Throughout Europe the break between the Pleistocene age represented in the cave by the bones in the clay and the Prehistoric age—the Neolithic of the cave—is so great and so full of difficulty that it cannot be gauged by any method which has hitherto been invented. Mr. Boyd Dawkins also exhibited a remarkably perfect javelin head of bronze which had been dug up in a field near Settle.—“Species viewed Mathematically,” by Mr. T. S. Aldis. We have learnt that all energy is really one, whether seen in heat, constrained position, or motion. Many also believe that life is really one, whether seen in man or a toadstool. But for our part we have often felt a difficulty. Why, if all life be one, do we not see it passing through every variety of form instead of being restricted to certain well-defined types? The present paper is an attempt to explain this. Let us consider what Plato might have called the *αὐρογενὲς* or complete type of animal. It consists of a certain definite number of organs, composed of a certain definite number of parts. It will also have certain ailments, location, enemies, &c., which we may call its province, necessary for its life. Thus our type animal is capable of a flux passing through all possible forms and provinces in all possible combinations. I include amongst these, of course, many arrangements necessarily absurd. To each arrangement of organs and provinces thus imagined would correspond a certain vitality or power of living in the type. I mean not merely power of individual existence, but existence as a race. The vitality is therefore a function of a large number of variables, some independent, others connected by equations of condition. It is to us quite an unknown function, but not therefore indefinite. Therefore, as in any other function of variables, certain relations amongst the variables will give maxima values of the vitality. These maxima of vitality constitute species. Vitality is not mere physical might or agility or fecundity, but compounded of all. Now for a maximum, we know that any change in the variables lessens the function. We thus see how species are stable. In the constant variation, for no being seems capable of reproducing itself exactly, all individuals have less vitality as they depart from the special type which gives the maximum of vitality, and will be choked out by those which, being nearer to the type, possess more vitality. So hybrids, intermediate between two maxima, will possess less vitality than either, and will be choked out, though the main cause of failure is that the process is like that devised by Swift's Laputan philosopher, who sawed the Whigs' and Tories' heads in half, and changing them, left each brain to settle its politics in itself. So the poor mule, with a bundle of habits, half horse and half ass, in this intestine conflict, has little power to take care of itself. Of course all maxima may not have plants or animals representing them. If there be several maxima suited for nearly the same province, the maximum of greatest intensity will choke out the others. So, too, there are probably many maxima now unoccupied, as, for instance, the thistle represented a maximum of vegetable life in South America, but till man imported the thistle to fill it up, other maxima of less intensity held the ground. In some cases possibly several maxima are closely related, and differ little in their intensity, so that slightly differing species exist together, and may in their variation pass one into the other, as perhaps in brambles and some species of St. John's wort, &c. If then the province of a species, *i.e.*, the physical geography of

a country, alter, and its enemies and food with them, clearly the maximum will shift and the species change. But this is not the evolution of new species, though to a person who only notes geological evidence it appears so. For, just as in a storm the lightning shows the trees still, though really waving to and fro, so the different species in geology are probably but steps in a constant change. Such a change of course must be slow for life to follow it, for a species consists quite as much in a bundle of acquired and transmitted habits as in a certain formation of organs, and the change in habit will probably be far slower than the change in form. How then do new species arise? For we see that, if the species be a maximum of vitality, in a multitudinous progeny those nearest the type will choke out the others, and the species will be stable. Varieties will be connected with maxima of vitality in two ways. Firstly, slight differences in the province will slightly shift the maximum. Thus mountain sheep would be more agile than lowland sheep. Secondly, in such a way as this. Suppose this table a low mound, narrow though long. Then the height at any point will be a function of the distances from the north and east walls of the room. There will be one point of maximum height, but whilst a change north or south produces a great change in the altitude, one east or west will produce but little. So there will be variations in some characteristics which will produce little alteration in the whole vitality. Thus, amongst wild oxen probably no varieties without horns would exist, for they affect the vitality. Amongst protected races they do not, and so hornless varieties arise. Still these varieties are but varieties, and are not steps towards a new maximum which a gulf of lesser vitality still separates them from. Or let us consider the varieties that we try to make by select breeding. These are least of all likely to produce new species. We simply by main force depress vitality in removing individuals as far as we can from the normal type, and when the vitality is sufficiently depressed we can go no further. As for altering the province, the independent variables, so to speak, we know so little how to do it, and certainly could not do it gradually enough, that we have no chance in this way of effecting anything. How then can new species arise? Apparently in some such way as this, by what we may call the bifurcation of a maximum. If we drew a horizontal line along which the variation of the organs of an animal were expressed and the corresponding vitality were drawn by ordinates, we should get a curve we might call the vitality curve, whose maxima values would be species. As time elapses and the conditions of the earth, &c., alter, the constants, so to speak, of the curve alter, and we get our curve to vary and the maxima shift; and as the curve alters, one maximum may separate into two or more others, and thus in the lapse of time, one species may separate into two or more others. Roughly to illustrate it, suppose some species developed free from the influence of carnivora, and that, owing to various causes, size little affects its vitality, it may vary all through, from little and swift to big and heavy. Now, introducing carnivora, we can see how a bifurcation of our maximum would take place. The very light and swift would preserve themselves by their agility, the strong and heavy by their strength, whilst the intermediate would be killed out, and thus two distinct species would arise, which might in course of time by further variation separate still further apart. Doubtless, however, this bifurcation goes back to very remote times. Carnivores and herbivores probably separated not as mammals but as reptiles, or even long before, whilst ruminants and non-ruminants may have separated since they became mammals. Thus Australia seems to have possessed at one time only one marsupial, which has bifurcated into various marsupials, but not into any of another kind. The older the species grow, the deeper is the gulf between them, and, like a river, we have to ascend nearly to the source before we can make a passage from one bank to the other. To recapitulate—Maxima of vitality are species. Any alteration from the normal type produces less vitality, hence the normal type is stable. A slow change of physical geography, &c., slowly changes these maxima, and the species change with them, extinct species being generally glimpses of steps in this change. New species will generally arise from the bifurcation of maxima under circumstances over which man can exercise little control, and which, if he could, he would very likely alter so as either hardly to affect the maximum at all, or too rapidly for the species to shift with it. Selected breeding produces types of less vitality, and therefore will hardly produce new species. Thus the present stability of species is no argument against the doctrine of evolution.

GLASGOW

Geological Society, November 30.—Dr. Robert Brown, F.R.G.S., delivered a lecture on "Greenland; its Physical Geology and Fossil Flora." After alluding to the interest which Greenland possessed, as presenting a picture of what the British Isles were supposed to have been during the glacial period, Dr. Brown gave a graphic sketch of the coast scenery of the country, which he compared to a succession of islands with water on the one side and ice on the other. He described the interior of Greenland as one vast sheet of ice of great thickness, pressing out on all sides to the sea, and occupying as separate glaciers the fiords which indent the coast. These glaciers in many instances push their way out to sea, where portions are broken off and drift away as icebergs; in other cases, the glacier dissolves near the head of the fiord, and great stores of muddy water escaping from it form a deposit of fine clay, which has sometimes silted up part of the fiord so effectually as even to turn the glacier aside into another channel. From what he had observed in Greenland, he was inclined to hold that the lower till, or boulder-clay, as it exists in the Forth and Clyde valley, was formed by such a sheet of massive land ice slowly moving over the country, while what he had described as resulting from the waste of the glaciers near the sea might account for some of the well-known beds of laminated clay associated with that deposit. He questioned whether icebergs really did much in the way of conveying rocks or *debris* to any distance. So far as he had observed they bore wonderfully little of such material in or upon them; and he thought that to call in their agency, as had sometimes been done, to account for the dispersion of plants, &c., was highly visionary. Dr. Brown then alluded to the rock-formations of Greenland, and to the plant remains of the Carboniferous and middle Tertiary periods which had been found in the country, showing that it once enjoyed a very different climate from that to which it is now subjected. The Carboniferous plants had only been recently discovered by Dr. Pfaff, and he trusted that gentleman, who was resident on the spot, would be enabled to make further researches.

PARIS

Academy of Sciences, December 4.—M. Chasles presented a number of theorems relating to the harmonic axes of geometrical curves, and M. C. Jordan a paper on Gauss's sums with several variables. — M. Tresca read a paper on the effects produced during the planing of metals; and M. H. Resal communicated some investigations on the calculation of the fly-wheels of steam-engines.—Letters were read from Father Secchi on a new method of measuring the heights of the solar protuberances, and on the temperature of the sun. Upon the latter M. Faye made some remarks.—M. Le Verrier presented a note on the shooting stars of the month of November, from observations made in France and Italy. Many meteors issued from the constellation Leo, but the point of radiation was slightly displaced. Five or six currents of meteors in different directions were observed. In August a displacement of the point of radiation was observed between the 9th and 11th.—An extract from a letter from M. J. F. J. Schmidt to M. Delaunay on the November meteors observed at Athens was also read.—M. C. Saint-Claire Deville communicated a note on the early cold weather of 1871, which appears to have prevailed over the whole of France.—M. F. de Biseau recorded the observation of aurora borealis in Belgium on the nights of the 9th and 10th November.—A note from M. de Magnac on the determination by means of chronometers of the differences of longitude of distant places was read.—M. Lecoq de Boisbaudran presented a note on the separation and quantitative determination of some metals by means of a voltaic current.—M. A. Béchamp communicated some observations on a recent note by M. Ritter on the formation of u_{ea} by albuminoid materials and permanganate of potash.—M. Wurtz presented a note by M. L. C. de Coppet on a new method of preparing supersaturated saline solutions, in which the author stated that solutions identical with those called supersaturated could be prepared by dissolving certain dehydrated salts (sulphate and carbonate of soda) in cold water.—M. Peligot presented a note by M. T. Schlessing, containing a comparison of the two conditions of a soil in part wooded and in part cleared and treated with lime.—M. Peligot also presented a note by M. A. Renard on the determination of ground-nut oil in olive oil. The process, which is rather complicated, consists in the saponification of the oil, and the separation from the soap of the arachidic acid which is characteristic of ground-nut oil.—M. Balard communicated a note by MM. Scheurer-Kestner and C. Meunier

on the composition and heat of combustion of lignites, containing the analyses and results of combustion of six lignites from various parts of France, and from Bohemia. The heat of combustion was always found to be inferior to that of the carbon and hydrogen contained in the lignites.—M. Elie de Beaumont exhibited a collection of minerals from Bolivia, Chili, and Peru sent by M. Domeyko.—M. S. Meunier presented a note on a new method of obtaining Widmannstätten's figures by attaching a polished plate of meteoric iron to the positive pole of a Bunsen's battery and a plate of silver to the opposite pole, and plunging both into a solution of bisulphate of potash.—M. Husson communicated an analysis of the milk of cows attacked by contagious typhus.—A note was read on the Garumnian type of the department of the Aude, by M. A. Leymerie, in which the author maintains the distinctness of this geological stage, and indicates some of the fossils which characterise it.

THE COPLEY MEDALIST OF 1870

THIRTY years ago Electro-magnetism was looked to as a motive power which might possibly compete with steam. In centres of industry, such as Manchester, attempts to investigate and apply this power were numerous, as shown by the scientific literature of the time. Among others Mr. James Prescott Joule, a resident of Manchester, took up the subject, and in a series of papers published in Sturgeon's "Annals of Electricity" between 1839 and 1841, described various attempts at the construction and perfection of electro-magnetic engines. The spirit in which Mr. Joule pursued these inquiries is revealed in the following extract: "I am particularly anxious," he says, "to communicate any new arrangement in order, if possible, to forestall the monopolising designs of those who seem to regard this most interesting subject merely in the light of pecuniary speculation." He was naturally led to investigate the laws of electro-magnetic attractions, and in 1840 he announced the important principle that the attractive force exerted by two electro-magnets, or by an electro-magnet and a mass of annealed iron, is directly proportional to the square of the strength of the magnetising current; while the attraction exerted between an electro-magnet and the pole of a permanent steel magnet varies simply as the strength of the current. These investigations were conducted independently of, though a little subsequently to, the celebrated inquiries of Henry, Jacobi, and Lenz and Jacobi on the same subject.

On the 17th of December, 1840, Mr. Joule communicated to the Royal Society a paper on the production of heat by Voltaic electricity; in which he announced the law that the caloric effects of equal quantities of transmitted electricity are proportional to the resistance overcome by the current, whatever may be the length, thickness, shape, or character of the metal which closes the circuit; and also proportional to the square of the quantity of transmitted electricity. This is a law of primary importance. In another paper, presented to but declined by the Royal Society, he confirmed this law by new experiments, and materially extended it. He also executed experiments on the heat consequent on the passage of Voltaic electricity through electrolytes, and found in all cases that the heat evolved by the proper action of any Voltaic current is proportional to the square of the intensity of that current multiplied by the resistance to conduction which it experiences. From this law he deduced a number of conclusions of the highest importance to electro-chemistry.

It was during these inquiries, which are marked throughout by rare sagacity and originality, that the great idea of establishing quantitative relations between Mechanical Energy and Heat arose and assumed definite form in his mind. In 1843 Mr. Joule read before the meeting of the British Association at Cork a paper "On the Caloric Effects of Magneto-Electricity and on the Mechanical Value of Heat." Even at the present day this memoir is tough reading, and at the time it was written it must

have appeared hopelessly entangled. This I should think was the reason why Prof. Faraday advised Mr. Joule not to submit the paper to the Royal Society. But its drift and results are summed up in these memorable words by its author, written some time subsequently: "In that paper it was demonstrated experimentally that the mechanical power exerted in turning a magneto-electric machine is converted into the heat evolved by the passage of the currents of induction through its coils, and on the other hand, that the motive power of the electro-magnetic engine is obtained at the expense of the heat due to the chemical reaction of the battery by which it is worked."⁵ It is needless to dwell upon the weight and importance of this statement.

Considering the imperfections incidental to a first determination, it is not surprising that the "mechanical values of heat," deduced from the different series of experiments published in 1843, varied somewhat widely from each other. The lowest limit was 587, and the highest 1,026 foot-pounds for 1° F. of temperature.

One noteworthy result of his inquiries, which was pointed out at the time by Mr. Joule, had reference to the exceedingly small fraction of the heat which is actually converted into useful effect in the steam-engine. The thoughts of the celebrated Julius Robert Mayer, who was then engaged in Germany upon the same question, had moved independently in the same groove; but to his labours due reference will doubtless be made on a future occasion. In the memoir now referred to Mr. Joule also announced that he had proved heat to be evolved during the passage of water through narrow tubes; and he deduced from these experiments an equivalent of 770 foot-pounds, a figure remarkably near to the one now accepted. A detached statement regarding the origin and convertibility of animal heat strikingly illustrates the penetration of Mr. Joule and his mastery of principles at the period now referred to. A friend had mentioned to him Haller's hypothesis, that animal heat might arise from the friction of the blood in the veins and arteries. "It is unquestionable," writes Mr. Joule, "that heat is produced by such friction, but it must be understood that the mechanical force expended in the friction is a part of the force of affinity which causes the venous blood to unite with oxygen, so that the whole heat of the system must still be referred to the chemical changes. But if the animal were engaged in turning a piece of machinery, or in ascending a mountain, I apprehend that in proportion to the muscular effort put forth for the purpose, a *diminution* of the heat evolved in the system by a given chemical action would be experienced." The italics in this memorable passage, written it is to be remembered in 1843, are Mr. Joule's own.

The concluding paragraph of this British Association paper equally illustrates his insight and precision regarding the nature of chemical and latent heat. "I had," he writes, "endeavoured to prove that when two atoms combine together, the heat evolved is exactly that which would have been evolved by the electrical current due to the chemical action taking place, and is therefore proportional to the intensity of the chemical force causing the atoms to combine. I now venture to state more explicitly, that it is not precisely the attraction of affinity, but rather the

* Phil. Mag. May 1845.

mechanical force expended by the atoms in falling towards one another, which determines the intensity of the current, and, consequently, the quantity of heat evolved; so that we have a simple hypothesis by which we may explain why heat is evolved so freely in the combination of gases, and by which indeed we may account 'latent heat' as a mechanical power prepared for action as a watch-spring is when wound up. Suppose, for the sake of illustration, that 8 lbs. of oxygen and 1 lb. of hydrogen were presented to one another in the gaseous state, and then exploded; the heat evolved would be about 1° F. in 60,000 lbs. of water, indicating a mechanical force expended in the combination equal to a weight of about 50,000,000 lbs. raised to the height of one foot. Now if the oxygen and hydrogen could be presented to each other in a liquid state, the heat of combination would be less than before, because the atoms in combining would fall through less space.* No words of mine are needed to point out the commanding grasp of molecular physics, in their relation to the mechanical theory of heat, implied by this statement.

Perfectly assured of the importance of the principle which his experiments aimed at establishing, Mr. Joule did not rest content with results presenting such discrepancies as those above referred to. He resorted in 1844 to entirely new methods, and made elaborate experiments on the thermal changes produced in air during its expansion: firstly, against a pressure, and therefore performing work; secondly, against no pressure, and therefore performing no work. He thus established anew the relation between the heat consumed and the work done. From five different series of experiments he deduced five different mechanical equivalents; the agreement between them being far greater than that attained in his first experiments. The mean of them was 802 foot-pounds. From experiments with water agitated by a paddle-wheel, he deduced, in 1845, an equivalent of 890 foot-pounds. In 1847 he again operated upon water and sperm-oil, agitated them by a paddle-wheel, determined their elevation of temperature, and the mechanical power which produced it. From the one he derived an equivalent of 781.5 foot-pounds; from the other an equivalent of 782.1 foot-pounds. The mean of these two very close determinations is 781.8 foot-pounds.

At this time the labours of the previous ten years had made Mr. Joule completely master of the conditions essential to accuracy and success. Bringing his ripened experience to bear upon the subject, he executed in 1849 a series of 40 experiments on the friction of water, 50 experiments on the friction of mercury, and 20 experiments on the friction of plates of cast-iron. He deduced from these experiments our present mechanical equivalent of heat, justly recognised all over the world as "Joule's equivalent."

There are labours so great and so pregnant in consequences, that they are most highly praised when they are most simply stated. Such are the labours of Mr. Joule. They constitute the experimental foundation of a principle of incalculable moment, not only to the practice, but still more to the philosophy of Science. Since the days of Newton, nothing more important than the theory of which Mr. Joule is the experimental demonstrator has been enunciated.

I have omitted all reference to the numerous minor papers with which Mr. Joule has enriched scientific literature. Nor have I alluded to the important investigations which he has conducted jointly with Sir William Thomson. But sufficient, I think, has been here said to show that, in conferring upon Mr. Joule the highest honour of the Royal Society, the Council paid to genius not only a well-earned tribute, but one which had been fairly earned twenty years previously.*

Comparing this brief history with that of the Copley Medalist of 1871, the differentiating influence of "environment" on two minds of similar natural cast and endowment comes up in an instructive manner. Withdrawn from mechanical appliances, Mayer fell back upon reflection, selecting with marvellous sagacity from existing physical data the single result on which could be founded a calculation of the mechanical equivalent of heat. In the midst of mechanical appliances, Joule resorted to experiment, and laid the broad and firm foundation which has secured for the mechanical theory the acceptance it now enjoys. A great portion of Joule's time was occupied in actual manipulation; freed from this, Mayer had time to follow the theory into its most abstruse and impressive applications. With their places reversed, however, Joule might have become Mayer, and Mayer might have become Joule.

JOHN TYNDALL

THE BROWN INSTITUTION

IN 1852 a large sum of money was bequeathed by the late Mr. Thomas Brown to the University of London for the purpose of "founding and upholding" an Institution for "investigating, studying, and if possible endeavouring to cure" the diseases and injuries of animals useful to man. The sum was to be allowed to accumulate for a limited period, at the end of which the principal and interest were to be applied in the manner directed. And it was provided that in case the University should fail to carry out the trust imposed upon it within nineteen years after the testator's death, the whole sum with the accumulations should be transferred to the University of Dublin, to be applied for the endowment of certain philosophical professorships. The will contains various directions for the administration of the proposed Institution. The most important are those which relate to the appointment of a Committee of Management and of a Professor. The committee must be appointed by the governing body of the University, and must consist either of members of the Senate or of other persons, members of the medical profession. As regards the qualifications of the professor nothing is said. He must be appointed by the University, must give a course of lectures annually, and must have a residence adjacent to the Institution.

The nineteen years have now almost expired. In pursuance of the testator's directions, the "Brown Institution" has just been opened. Last summer a large plot of freehold land was acquired by the University in the Wandsworth Road, close to the goods station of the South-

* Had I found it in time, this notice should have preceded that of the Copley Medalist of 1871.

Western Railway. On this ground a Hospital for Animals has been built, consisting of stables for the reception of the larger quadrupeds, and of houses of various descriptions for those of a smaller size. All of these buildings are constructed in the best style, with a view to the well-being of the creatures they are destined to contain, being thoroughly drained, paved, and ventilated, and warmed with hot-water pipes. Adjoining them there is a spacious exercise ground.

As many of our readers already know, the Senate have placed the Institution under the management of Dr. Burdon Sanderson, of University College, London, who, as Professor, will, in future, deliver the annual course of lectures.

If the scope and purpose of the Brown Institution were limited to the care and cure of diseased animals, its establishment would scarcely be worthy of record in the pages of NATURE, for, however desirable it may be that the animals that serve us should be kindly and skilfully treated when they are sick, the object has so remote a relation to the promotion of physical science that our readers could not be expected to take any special interest in it. But, happily alike for humanity and for science, the late Mr. Brown showed by his selection of persons to be entrusted with the carrying out of his intentions, by the instructions contained in his will for their guidance, and by the terms in which he defined the purposes of the proposed Institution—placing study and investigation first, cure afterwards—that he was not actuated by a mere sentimental sympathy for the lower animals as such, but that he desired, by promoting the scientific study of their diseases, to benefit mankind.

As might have been expected, the Senate of the University of London have not only fulfilled the letter of the testator's dispositions, but have proved by the manner in which they have done so, that they are actuated by the same noble purpose. They have shown this first of all in their selection of a Committee of Directors. What could be a better guarantee for the future good administration of the Institution than the fact that among its directors are to be found such men as Busk, Carpenter, Gull, Paget, Quain, Sharpey, Sibson, and Simon, men eminent as physiologists, pathologists, or clinical teachers; of each of whom it may be said that he has contributed a large proportion to the total amount of work done in his own branch of science in England during the past thirty years. We do not think that it would have been possible, even if their choice had been perfectly unlimited, to have selected persons more fitted for the purpose, whether as regards personal character or scientific attainments.

Under the direction of Dr. Sanderson, a laboratory intended, to quote the terms of the will, "for the study and investigation of disease," has been built on the ground already referred to at Vauxhall, adjoining the hospital for animals. The laboratory consists of four admirably-lighted and spacious working rooms, connected by a corridor. Underneath these are four other rooms, which, although not so lofty, are also well adapted for many kinds of research. In the same building is included a stable for the reception of animals intended to be the subjects of special observation.

In the work of the laboratory the Committee of Direc-

tion have most wisely associated with Dr. Sanderson, under the title of Assistant Professor, Dr. E. Klein, whose name is well known as the contributor of valuable articles to Stricker's "Histology," and of several important embryological researches. Well trained as a pupil of Brücke and Stricker in the methods of research, whether physical, chemical, or microscopical, young in years though old in accomplished work, Dr. Klein is singularly fitted for the post. Dr. Sanderson is much to be congratulated in having so able a coadjutor.

It may not be out of place if we attempt to give our readers an idea of the work which we suppose will be done or attempted in the laboratory of the Brown Institution.

The facts on which the science of disease, so far as it may as yet be called a science, is founded, are gathered from two sources, the bedside and the laboratory. In clinical studies the same, or even greater, exactitude is required as in those of the physicist or chemist; but even when they are conducted in the wards of a hospital, the Harveian method of "searching out the secrets of nature by way of experiment," can only be applied under limitations which very materially embarrass the inquiry. The pathologist at the bedside is not in the position of an experimenter, but only in that of a student, who stands by at a greater or less distance, while another, over whom he has no control, performs experiments in his presence, without deigning to explain to him their nature or purpose. The true physician fears to meddle with the processes of which he is the attentive and anxious spectator. Although the more ignorant members of the medical craft—the so-called "practical" men—may sometimes, with the best intentions, experiment on their patients with harmful drugs, such experimentation is repudiated by the man of science.

There are, however, many questions relating to disease, of the most profound importance to the human race, which cannot be solved, and never will be solved, by thus, as it were, standing on one side and watching what goes on at a distance; such questions, for example, as the nature of contagion, and those which relate to the origin and proximate causes of our most common diseases, such as inflammation, fever, and tubercle. The knowledge which has been acquired on these subjects during the last few years has been gained by work done in laboratories. The advantages of this mode of inquiry, as compared with the indirect clinical method, are of two kinds—the one relating to the objects of observation, the other to the means which are at the disposal of the inquirer. In dealing with animals, he is embarrassed by scarcely any of the limitations which render clinical observation so difficult. The very considerations, indeed, which in the case of man, absolutely forbid his entertaining any other purpose excepting that of prolonging life and alleviating pain, not only allow, but encourage him, in the case of animals, to disregard altogether the present suffering for the future benefit. We are clearly justified in profiting by the sufferings of the lower animals for man's sake. We may subject them experimentally to the action of remedies without any immediate view to their being thereby benefited. We may place them under conditions which we know will produce disease, for the purpose of studying the mode of action of those conditions. We have

at least as good a right to kill sick animals for the purpose of investigating the anatomical changes produced by disease, as to slaughter healthy animals for food. And even if in the pursuit of our inquiries we are compelled to inflict pain, we are perfectly right in doing so—provided that truths valuable to humanity are to be learnt by it.

The other respect in which the comparative pathologist has an advantage over the clinician, lies in the choice of means. It is true that during the last few years much progress has been made in the application of instruments of precision to the investigation even of human diseases; but, after all, there are few of those instruments which are really valuable. In the case of animals it is entirely different. The microscope may be applied to the investigation of tissues unaltered by those changes which speedily follow the extinction of life. The measurement of the temperature of the body, whether with relation to the changes which it undergoes in disease, or to the differences between diseased and healthy parts, can be performed in animals with all the exactitude which such investigations require—in man such exactitude is impossible, because the conditions of observation cannot be controlled. Instruments of precision may be used for the investigation of the changes which disease produces in the mechanical functions of respiration and circulation, which, for reasons already adverted to, could not be applied in the sick room, or in the wards of a hospital—and if they were applied, would yield no satisfactory results.

Again, in animals it is possible to apply the ordinary methods of chemistry to investigate the modifications produced by disease in the process of nutrition; whereas in man this is attended with such insuperable difficulties, that it may be regarded as impossible.

Many other similar examples might be mentioned; but these may serve to explain the way in which we hope to see the new laboratory at Vauxhall brought into relation with the hospital for sick animals. Believing that the study of pathology, like that of physiology, of which it forms part, can only be successfully prosecuted by observing the operation of chemical and physical laws in the living diseased body, and applying the same methods as are used by the chemist and physicist to their investigation, and that the more this principle is acted on, the more rapid and solid will be the progress made, we regard the establishment of the Brown Institution as an important step in the right direction. We should have been still better pleased if it had been a laboratory of physiology, for this ought to have preceded the other. We think it, however, not unlikely that it may, by setting an example of good work, exercise a considerable indirect influence in the promotion of physiological studies in this country.

We must not omit to mention that although the laboratory is intended for research rather than for instruction, it will be open to those who may wish to engage on their own account in scientific inquiries. The only condition imposed by the directors on those who desire admission to the laboratory as workers, is the possession of "previous scientific training." Each worker will have to defray the expenses of material, but no other payment will be required of him. It is understood that the laboratory will be opened on the 1st of January, 1872.

FOREIGN YEAR-BOOKS

Jahrbuch der Erfindungen. Herausgegeben von H. Hirzel und H. Gretsche. Sechster Jahrgang. (Leipzig: Quandt und Händel; London: Williams and Norgate, 1870; pp. 472.)

THE sixth volume of this series fully sustains the high character achieved by its predecessors. Astronomy, physics and meteorology, mechanics and mechanical technology, and chemistry and chemical technology form the subjects of the respective chapters.

We cannot open any part of the work without observing the care with which it is edited. We shall select for special notice the latter part of the chapter on chemistry, which treats of organic compounds, beginning with the following paragraph upon the products of oxidation of paraffin. After describing the recent improvements introduced by Hübner in the preparation of this substance from coal-tar, and in its mode of purification, and noticing its remarkable stability (it being unaffected by concentrated hydrochloric or sulphuric acids, and by the alkalis), the reporters state that there are certain oxidising agents, and especially chromic and nitric acids, which it is unable to resist. Gill and Meusel have studied the action of these reagents on paraffin, and have arrived at the following results:—

"The paraffin in common use fuses at 56° C., and by repeated crystallisation from sulphide of carbon the fusing point may be raised to 60° and upwards. If we boil from 300 to 500 grammes of pure paraffin with 120 grs. of bichromate of potash, and 180 grs. with sulphuric acid diluted with twice its volume of water for three or four days in a glass retort till the chromic acid is completely reduced to chrome-oxide, acetic acid and other acids of the same series, and principally cerotic acid, are formed; the latter being a white solid substance that does not fuse at a lower point than 78° C., and also occurs as a main constituent of bees'-wax. If we boil paraffin continuously with five or six times its volume of nitric acid of 1.3 sp. gr., which has been previously diluted with 1½ times its volume of water, we likewise obtain cerotic acid, in addition to acetic, butyric, valerianic, and succinic acids, and other products" (p. 261).

Passing over a section on "Fats, fatty oils, and allied substances, and the products of their decomposition," in which is a notice of the explosive compounds derived from glycerine, we come to one treating of "Resins," in which there is a notice of Puscher's interesting and highly-practical communication on shellac-ammonia solutions. Perhaps the most valuable of the applications of these solutions is their property of dissolving certain of the aniline colours, as aniline green, aniline yellow, and fuchsin.

The organic non-nitrogenous acids, the carbo-hydrates, alcohol and its products, the albuminous bodies and their allies, newly-discovered organic bases, pigments and pigment-yielding bodies, both natural and artificial, nutritious matters, and disinfectants, are all duly considered. The report on artificial pigments is especially deserving of commendation. It consists of nearly fifty pages full of practical matter, and, taken in conjunction with a previous report that appeared in the second volume (for 1866), forms the most complete summary of this important department of practical chemistry, that, taking its limits into consideration, we are acquainted with.

As usual the volume concludes with a necrology for the past year.

OUR BOOK SHELF

Marvels of Pond-Life: or a Year's Microscopic Recreations among the Polypts, Infusoria, Rotifers, Water-Bears, and Polyzoa. By Henry J. Slack, F.G.S., &c. Second Edition. (London: Groombridge and Sons.)

THIS little volume is already so well and favourably known to microscopists that any formal notice or commendation is scarcely necessary. Professing only to be a first book on "Pond-Life," it does not attempt more than to guide the young student in searching after, collecting, and examining the various animal organisms which inhabit fresh water. The division into months indicates that it is also popular rather than abstruse, and the number of species mentioned or figured is very limited. There appears to be no good reason why the present edition should not have made an advance beyond its predecessor, and given us an additional chapter or two on the construction and management of small aquaria at home, adapted especially and entirely to minute pond-life, by means of which metropolitan students might continue the study when unable to go to the ponds; and also on those artificial ponds for the evolution of Infusoria, so much alluded to of late, infusions of organic substances. Keeping in view the simple pretensions and elementary character of this volume, it fully answers the design of its author, and we are glad to announce the appearance of a second edition.

Physikalisches Repetitorium, &c., &c. Von Dr. Ferdinand Bothe. Second Edition, revised and enlarged. (Brunswick: Vieweg, 1871.)

A BRIEF enumeration of the more prominent facts and formulae of physics; carefully divided into subjects, and with occasional dates and names of inventors or discoverers. We conceive that to make an excellent work of this kind (if such a thing be at all desirable), all that is necessary, is to take a really good treatise on natural philosophy and construct something between an Index to, and an Abstract of, its contents. It seems probable that some such process has been employed by Dr. Bothe; but either he cannot have used a trustworthy book for analysis, or his analysis is not a faithful one. In fact, if we look on it seriously, a more painful volume we have not often met with; nor a more amusing one, if we could fancy its blunders intended to amuse. We simply open its pages at hazard, and make a few pickings:—

"64. The density and resilience (*Spannkraft*) increase in proportion to the pressure, the volume is inversely as the pressure, and *vice versa*—Boyle's or Mariotte's Law, 1679." James Bernoulli was a contemporary of these men, and says in his work, "*De Gravitate Aetheris*," "*Veritas utriusque hujus regulæ manifesta fit duobus curiosis experimentis ab Illust. Dn. Boyleio hanc in rem factis, quæ videlis [sic] in Tractatu ejus contra Linum.*" The date of this tract of Boyle's is 1662, and it is to be observed that Bernoulli does not mention Mariotte at all. We notice, in passing, that Young's name is not mentioned under Capillarity, and we arrive at the following curiosity:—"140. Unit of momentum or of work (*Arbeit*) is the force (*Kraft*) which can in one second communicate to unit of weight a velocity of unit of length. (Its metrical measure is the kilogramme-mètre; in Prussia, England, &c., the foot-pound." But we beg Dr. Bothe's pardon. We had no right to render *Arbeit* by "work," which is its usual equivalent in scientific books; for looking back we find:—"129. The product of the weight of a body into its velocity is called Momentum, and also *Arbeit*!" It is scarcely possible to conceive a more hopeless jumble of essentially different things than these sentences exhibit. The Heliotrope is (468) ascribed to Gauss, 1830 (?). Did not Drummond use it in 1826? 471 gives Bunsen and Kirchhoff the credit of the spectro-scope, with its collimator, &c. What of Swan? As to the

equality of absorption and radiation, Angström is given without date, Stokes and Balfour Stewart not mentioned. "472. The planets and comets (!) send back only the rays which the sun has sent to them." 484. In the enumeration of the earliest attempts to produce photographic impressions, there is no mention of Wedgwood, &c. 558. No mention is made of Northmore, whose long priority in the liquefaction of gases was insisted on by Faraday. 592. The old story of Mayer and the dynamical theory of heat. His date is given as 1842; Davy and Rumford (who did all that is referred to in the text more than forty years before) are not mentioned. Joule is coupled with Clausius, and the date 1853 is assigned to them! Of Carnot, Colding, Rankine, Thomson, &c., not a word. 598-600. The experimental laws of heat of combination are very imperfectly given, and, without any mention of Andrews and Hess, handed to Thomsen and Favre and Silbermann, with the date 1853! 666. The similarity of the order of bodies considered separately as conductors of heat and electricity is given to Wiedemann and Franz in the same prolific year. Surely Forbes pointed it out twenty years earlier! So far as we have seen, Sir W. Thomson, Clerk-Maxwell, &c., are not even named in the book.

If the reader remember that these are merely the things which have caught our eye in turning over the pages at random, he will not blame us for absolutely declining to examine the work more closely. A series of working tables is appended, but without very close examination we should hesitate to trust them, after what we have seen of the character of the book. That we have noticed it at all is due to the circumstance that some consolation is to be derived from the mere fact of its existence. We are all (in consequence, perhaps, of recent events) more or less imbued with the notion that Germany (Prussia especially) is rapidly taking the lead in matters of scientific education and investigation; and no doubt there is some truth in this. But the game is not lost, we are not yet passed in the race, and our old supremacy is quite within our reach even now, provided we make speedy and sufficient exertions to regain and maintain it. It will not drop into our mouths for a mere wish; but is it reasonable to wonder at the state of science in this country, where so few statesmen pay the least attention to it, when we find that even in enlightened Prussia, such a book as the above can be written by a recognised teacher, and published in a second edition by one of the highest firms in the world?

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Proof of Napier's Rules

I AM greatly obliged to "J. J. W." for pointing out the objection of a want of generality in the construction of the figure contained in my former letter (in NATURE, No. 106), for the proof of Napier's Rules; which the more general construction now described by "J. J. W." most simply and most effectually removes. To illustrate his more perfect general construction with a figure—D is the centre, and B12B' a part of the circumference of a circular piece of cardboard, upon which the arcs B1, 12 are taken equal to the sides of the right-angled spherical triangle which it is required to represent. If we join DB, D1, D2, and draw BC, CA perpendicular to D1, D2, the latter perpendicular prolonged meeting the circle of the circumference in B', and join DB'; and on AB' as diameter describe the semicircle AC'B'; and with the centre A, and radius AC, another circle, meeting the semicircle in C', so that the straight line AC' is equal to AC; and join B'C'. Then it is easily shown that if ACB are the two sides, AB' is the hypothenuse of a right-angled triangle, which, when the four triangles are closed together so as to form a solid figure, will coincide with the triangle AC'B'. As BC (or B'C') will then be perpendicular both to CD and to CA (or C'A), it will be perpendicular to the plane DCA; and the

are B_1 , which is in the same plane with it, will be at right angles to the arc 12. The third arc $2B'$ will therefore be the hypotenuse of a right-angled spherical triangle, of which B_1 , 12, are the two sides. Calling these arcs or the angles of the faces represented by them, α, β, γ , and the angles opposite to them in the spherical triangle, A, B, C , the proof of Napier's Rules, with this solid figure, proceeds by the same direct steps as those already described, with a special example of the figure in my former letter. As the construction there described is confined to the representation of a particular kind of right-angled spherical triangle, and is therefore inapplicable to illustrate the proof of

Napier's Rules experimentally in every given case, the general construction supplied by "J. J. W.," which is limited by no such restrictions, and which is at least equally convenient, will evidently serve more effectively the same practically useful and instructive purpose.

Instead of "accessible," as applied to the difficulties of the geometrical proofs produced by Mr. Cooley in his letter on "Elementary Geometry" (in *NATURE*, No. 103), which are indeed there obviously overcome, I would have used the word "surmountable" as more descriptive of geometrical difficulties, properly treated and discussed, had the word immediately presented itself to me; but having often found an easily executed model extremely useful and convenient in practical applications of Napier's Rules, with whose design, as a general resource to facilitate their study, I was not, however, so fully satisfied, I applied, perhaps unconsciously, to Mr. Cooley's demonstrations a term expressing strictly only the diffidence with which I ventured to present to readers of *NATURE* my own very imperfect geometrical contrivance. In thus making my difficulties accessible to "J. J. W.," I very gratefully acknowledge the assistance which I have derived from his remarks on my letter in *NATURE*, No. iii., and I cheerfully admit the merit and superiority of the general rule for constructing a proper model in cardboard, to illustrate the proofs of Napier's Rules, and to facilitate their study, which he has kindly consented to describe.

Newcastle-on-Tyne, Dec. 16

A. S. HERSCHEL.

Alternation of Generations in Fungi

I AM sure that the Rev. M. J. Berkeley will exonerate me from any deliberate intention to misrepresent him; nor do I think that there is, after all, much difference of opinion between us regarding the present subject, unless, perhaps, that I am more sceptical. I alluded to the paper cited by him from the "Journal of the Horticultural Society," on propagation of bunt spores, and not to his communications on the hop or vine mildew. I was under the impression that he regarded the "four consecutive forms of reproductive cells in the bunt" as an instance of alternation of generations. On reference to the original paper, I find that he did not go so far then as to indicate four consecutive forms of reproductive cells; but that Tulasne followed on his track in 1854, and in 1857 Mr. Berkeley seemed to have accepted the results of Tulasne's observations, since, in his "Introduction," he gives figures at page 318, in the description of which the following phrases occur:—"spores of the second order," "spores of the third order," "spores of the fourth order." Here are the "four consecutive forms of reproductive cells" to which I alluded. At page 321 he writes concerning the bunt:

"The spores, however, are not immediate means of propagation; they are, in fact, only a sort of prothallus, from which the mycelium grows, producing at the tips, or on lateral branchlets, bodies of various forms, which are themselves capable of germination, and immediately reproduce the species." The real issue between us seems to lie in the phrase, "alternation of generations." If the bunt spores, on germination, produce fusiform bodies, which, after conjugation, produce short cylindrical spores, and thus intermediate reproductive cells unlike the parent cell come between that and the ultimate reproduction of the species, I am induced to call it an "alternation of generations." It would be waste of time to discuss phrases, or I might take exception to the application of this phrase to the *Erysiphe*. The conidia and pycnidia of the hop mildew may be developed without sporangial conceptacles, and the parasite reproduced without sporangial fruit, but I cannot recognise alternation of generations in the reproduction of a species by means of conidia, stylospores, or sporidia, or by one of these alone. If such may be construed into an alternation of generations, it must be by permitting greater elasticity to the phrase. Conidia germinating and producing pycnidia, the stylospores of the pycnidia germinating and producing sporangial conceptacles, containing the sporidia which, upon germination, will produce the mycelium and conidia again, returning to the original form after two or three consecutive departures from it, appears to me a perfect type of alternation of generations. I fully admit that "if it is once established that a Puccinia produces an *Ecidium*, or an *Ecidium* a Puccinia, we should have a clear case, especially when the third form reverts to the first again." Without the slightest desire to "depreciate the labours of Oersted and De Bary," I cannot admit that they have established facts until their observations are confirmed, especially when there is an evident possibility of their having been deceived. I shall have no hesitation in accepting the facts when they are confirmed by independent and equally trustworthy observers, although I may be unable to account for some of the phenomena. At present I must confess that I am not so sanguine as Mr. Berkeley appears to be.

The correspondent signing himself "Mycelium" wishes to know if "the liability to produce parasitic fungi is communicated from the seed to the mature plant." In some instances we know such to be the case, in others perhaps only suspect it. The "bunt" is an instance, or why the steeping of seed corn? or how did the Rev. M. J. Berkeley succeed in producing bunted wheat plants from seed corn inoculated with bunt spores? Two or three years since I published particulars of a similar instance of celery seed and *Puccinia Apii*. It would be as rash to affirm that this is always the case as to deny its occurring at all.

M. C. COOKE

In Re Fungi

THE letters in your last two numbers have reminded me how ill this subject is studied by some botanists in this country. I will give two recent instances: 1. In the last number of the *Journal of Botany*, p. 383, it is positively stated that *Agaricus artilinguis* (a rare and very critical species by the way) was determined by a growth which is there described a mere mass of mycelium. He must have been a bold man who ventured to name an agaric (above all things) from a mass of mycelium. 2. In the first number, October 1871, of the new edition of "Paxton's Botanical Dictionary"—"enlarged and revised"—under the article *Agaricus* there is to be found such a collection of obsolete names and absurd errors as to make the article simply ridiculous.

W. G. S.

Mr. Lowne and Darwinian Difficulties

MR. LOWNE (*NATURE*, December 7) sees no difficulty whatever in explaining by what natural process an insect with a succorial mouth is developed from one having the mandibular type of mouth, but still he does not explain. He affirms there is no doubt that "the pupa state is a modification (!) of the ordinary process of skin shedding," and that this is "proved" by so many facts that he cannot understand how it could be "denied," &c., but he does not prove it.

For aught I can tell, every internal tissue and every external scale of the butterfly may be represented in the larva; but I do not know and cannot prove that this is so, nor do I believe any one can prove it. That the changes which take place during the pupa state are very different from those that occur during any portion of the larva period, will be admitted by every one who

has kept silkworms or bred butterflies. The assertion that there is absolutely only a difference in the time at which the successive skins are formed in this and in ordinary ecdysis, is but assertion on the part of Mr. Lowne. Indeed, controversy becomes profitless if authority is to be substituted for fact, and an attempt made to silence opponents and stop inquiry by such positive assertions as the above and the following:—"The imaginal skin is likewise derived from cells laid down in contact with the imaginal discs." If Mr. Lowne were so good as to explain what no books tell me, and I fail to make out myself, I will study what he says with great attention, and thank him heartily. He knows me well enough to feel assured that I would do so; but it is useless, and he must permit me to say that it is not in good taste, for him to comment about the "return of darkness," and to use expressions more positive and arbitrary than are called for.

Let us, if we can, get at the facts concerning some of these marvellous changes. For this there is nothing like discussion, carried on with care and consideration, even for an opponent; and though the fittest may be certain that he will survive, don't let any one be in too great haste to proclaim himself either survivor or fittest, or call himself strong and others weak, as has been done once already by one distinguished evolutionist. Evolution is a much quieter and far more complex process than some enthusiasts would have us believe.

Mr. Lowne appeals to the fly. By all means let the fly be the subject of our inquiries. Of this creature he says, the nervous system undergoes *modification* but not *degeneration*. Now I ask, what part of the nervous system that is present in the maggot can Mr. Lowne find in the fly? I have studied both fly and maggot carefully, have worked at the matter long, and have utterly failed to find a trace of the nerve tissue of the maggot in the fly. Not only so, but I find the nerves of the fly as different as are the muscles from those of the maggot. The latter are altogether distinct in structure and in action. They contract at a very different rate, and are very different in many particulars.

Again, I must ask Mr. Lowne if he has seen any vestige of the mouth organs in the larva, for he says:—"It is the mouth organs of the larva which are new formations, not those of the imago." I have failed in my attempts to find any traces. There are other assertions about the alimentary canal and the sexual organs which are not proved. Does Mr. Lowne mean to say, for instance, that he or anyone else can adduce any reliable observations to prove that "the sexual organs are gradually developed, even from the time when the embryo is enclosed in the egg"? On p. 112 of his book on this very matter he says that he has not been able to verify Dr. Weissmann's assertion as to their presence, even in the larva; and now he suggests they exist in the egg!

But I must ask Mr. Lowne to explain what he means by saying in his letter, that it is an "utter mistake to suppose that any insect is re-developed during the pupa state," and that the nervous system "never undergoes degeneration," because on p. 116 of his own book, published only last year, I find the following passage: "All the tissues of the larva undergo degeneration, and the imaginal tissues are re-developed . . . under conditions similar to those appertaining to the formation of the embryonic tissues from the yolk!"

LIONEL S. BEALE

The Auditory Nerves of Gasteropoda

In your issue for October 26, I notice an account of Leydig's recent paper on the auditory organ of the Gasteropoda, which, though excellent in other respects, has an error of omission which I should like to see rectified. When so important a discovery for morphology is discussed as that of the innervation of the otolithic sac from the supra-oesophageal in place of the sub-oesophageal ganglion which is its apparent connection in all Gasteropoda (excepting the Heteropodous forms), the credit of it should be given to the right man. That man is the most eminent and accurate of French comparative anatomists—M. Lacaze-Duthiers. Prof. Leydig states in the beginning of his own paper that Lacaze-Duthiers' statements on this subject (published in the *Comptes Rendus* about three years ago, if my memory serves me, and curiously mistranslated, *sub-oesophagien* being rendered *sub-oesophageal* in one of the first numbers of the Monthly Microscopical Journal), caused him to direct his attention again to this subject, and he has, as a result, confirmed the observations of the French *savant*, which were in opposition to the previously-received views of all observers, himself and Leydig included. Germany has a host of indefatigable anatomists, and the services of Franz Leydig, of Tübingen, are brilliant enough to eclipse most zooto-

mical reputations; but let us not, at this moment above all others, forget to do justice, when the opportunity occurs, to a naturalist whose comprehensive, accurate, and beautiful zoological monographs, rich in discoveries, have done more than those of any other Frenchman to sustain the great name of Cuvier's school.

Naples, Dec. 8

E. R. LANKESTER

DR. CARPENTER AND DR. MAYER

AT the Anniversary Dinner of the Royal Society on November 30, I was honoured by a request from the President to say a few words in acknowledgment of the toast to the Copley Medalist. I did so, stating briefly the origin of my acquaintance with Dr. Mayer's writings. Though Dr. Carpenter at the time was within sight of me, it did not occur to me to introduce his name into my remarks. A few days afterwards I was favoured by a letter from Dr. Carpenter, in which he reminds me somewhat sharply of this and other lapses; as regards himself, and requests me to rectify the omission by a brief communication to the *Athenæum* or to NATURE. It will be fairer to Dr. Carpenter, and more agreeable to me, if he would state his own case *in extenso*. Here is his letter:—

"University of London, Burlington Gardens, W.,
December 5th, 1871.

"MY DEAR TYNDALL,—If I correctly apprehended what you said at the Dinner of the Royal Society in regard to Dr. Mayer, you repeated what you had previously stated in your Lecture at the Royal Institution in 1863, as to the entire ignorance of Mayer's work which prevailed in this country until you brought it into notice on that occasion.

"Now, I very distinctly remember that a few days previously to that Lecture, I mentioned to you that as far back as 1851 I had become acquainted, through the late Dr. Baly, with one of Dr. Mayer's earlier publications; and that, in bringing before the readers of the *British and Foreign Medical Review* (of which I was then the Editor) the 'Correlation' doctrine, as developed in Physics by Grove, and in Physiology by myself, I had stated that we had both been to a great extent anticipated by Mayer—as I should have shown much more fully if the pamphlet had earlier come into my hands.

"I also most distinctly remember that, as you stated in that Lecture, no one in this country—not even Sir Henry Holland, who knows everything—had ever heard of Mayer, I spoke to you again on the subject a few days afterwards; and that you then expressed your regret at having entirely forgotten what had previously passed between us on the subject.

"As it would seem that this second mention of the matter has also passed from your mind, I shall be obliged by your looking at the passages I have marked in pp. 227 and 237 of the accompanying volume, from which I think that you will be satisfied that I had at that date correctly apprehended Mayer's fundamental idea, and that I have done the best to put it before the public that I could under the circumstances—the article having been in type and ready for press before his pamphlet came into my hands.

"Since, in thus bringing forward Mayer, I spontaneously abdicated the position to which I had previously believed myself entitled, of having been the first to put forward the idea that all the manifestations of Force exhibited by a living organism have their source *ab extra*, and not—as taught by physiologists up to that time—*ab intra*, I venture to hope that you will do me the justice of stating the real facts of the case in a short communication either to the *Athenæum* or to NATURE.—I remain, my dear Tyndall, yours faithfully,
"WILLIAM B. CARPENTER

"Prof. Tyndall."

This letter was accompanied by a volume of the *Medico-Chirurgical Review*, containing an article headed, "Grove, Carpenter, &c., on the Correlation of Forces,

Physical and Vital." As I am very anxious that my *amende* to Dr. Carpenter should be all that he could desire, I shall deem it a favour to be permitted to publish in NATURE the passages to which, by marginal pencil marks, he has directed my attention. The first of them is this:—

"We now come to the memoir 'On the Mutual Relations of the Vital and Physical Forces,' communicated to the Royal Society by Dr. Carpenter, which bears date June 20, 1850, and which is published in the 'Philosophical Transactions' for last year. This, we believe, is the first systematic attempt that has been made, in this country at least, to work out the subject, and, as it is mainly an expansion of the ideas which had been put forth in our own pages at the beginning of 1848, the author may claim priority as regards the enunciation and development of the idea, both of Dr. Fowler and Dr. Radcliffe, although to a certain degree anticipated by Mr. Newport. We shall presently find, however, that both these gentlemen were themselves anticipated in a quarter they little guessed, and the whole case is obviously one of a kind of which the history of physiology as well as of other sciences furnishes many examples, in which a connecting idea, developed in another department of inquiry, struck many individuals at once as applicable to the same class of facts, and was wrought out by them in different modes, and with various degrees of success, according to their previous habits of thought."

The impersonal way in which this and other passages of the article distribute merit among scientific authors caused me to ask Dr. Carpenter who wrote it. His reply to me was "I thought I had made it sufficiently plain to you that the article was written by myself."

Here follow the other marked passages quoted in full:—

"We must not omit, however, to give our readers some account of the remarkable production of Dr. Mayer, who seems to have arrived at conclusions in all essential respects similar to those of Prof. Grove and Dr. Carpenter previously to the publication of the first edition of the 'Correlation of the Physical Forces,' though subsequently to the delivery of the lectures in which Prof. Grove first announced his views and to the publication of the abstract of them. Of the existence of this treatise we have only recently been made aware, and we venture to affirm that Prof. Grove and Dr. Carpenter were alike ignorant of it. We bring it before the public now, both as an act of justice to its author, and also because it affords additional evidence in favour of the Correlation doctrine, that it should have been independently worked out by a clear and intelligent thinker."

"The first part of Dr. Mayer's treatise is concerned entirely with physical forces. He starts with the two axioms, 'Ex nihilo nil fit,' and 'Nil fit ad nihilum,' and founds upon abstract considerations his first argument for the unity of force, and for the convertibility of those which are commonly accounted distinct forces. Of this convertibility he then proceeds to adduce experimental proof, in very much the same mode with Prof. Grove, and he at last arrives at the following scheme expressive of their relations.

- | | |
|---------------------------|---|
| 1. Force of Gravity. | } Mechanical Force. |
| 2. Motion. | } Mechanical Effect. |
| A. Simple. | |
| B. Undulating, vibratory. | |
| Imponderables. | { 3. Heat. |
| | { 4. Magnetism, Electricity, Galvanic current. |
| | { 5. Chemical decomposition of certain elements. |
| | { Chemical combination of certain other elements. |
| | Chemical Force. |

"He then passes on to the study of vital phenomena, and he finds, like Dr. Carpenter, the source of all change in the living organism, as well animal as vegetable, in the forces acting upon it *ab externo*; whilst the changes in its own composition he considers to be the immediate source of the forces which are generated in it. He does not enter, like Dr. Carpenter, into an analysis of the phenomena of growth and development, but fixes his attention rather upon the production of heat, light, electricity, and (above all) motion by living bodies, and aims to show that all these forces are developed in the course of material changes in the organism, and hold a certain definite relation to them. On these points his exposition is very full and complete, and the perusal of his essay will amply repay any who desire to see how much may be done in imparting precision and clearness to physiological reasoning by minds trained in the school of exact science."

To these passages I would add one other brief quotation regarding the conversion of heat into electricity:—

"Of the production of electricity by heat, the phenomena first brought into view by Seebeck, and known under the name of 'thermo-electricity,' afford the most characteristic example. When dissimilar metals are made to touch, or are soldered together, and are heated at the point of contact, a current of electricity is set in motion, which has a definite direction according to the metal employed, and which continues as long as an increasing temperature is pervading them, ceasing when the temperature is stationary, and flowing in the contrary direction whilst it is decreasing" (pp. 213-14).

Having thus, it may be tardily, done justice to Dr. Carpenter, a very few words regarding his letter will complete the subject.

1. Dr. Carpenter has *not* correctly apprehended what I said at the dinner of the Royal Society in regard to Dr. Mayer. Neither at that dinner nor on any other occasion did I say that the ignorance of Mayer's labours in this country was "entire."

2. I have not been altogether unmindful of Dr. Carpenter's desire to have his name mentioned in connection with this subject. In the printed report of the lecture referred to by Dr. Carpenter, delivered not in 1863 but in 1862, and published in the Proceedings of the Royal Institution for that year, these words appear—"Mayer's physiological writings have been referred to by physiologists—by Dr. Carpenter, for example—in terms of honouring recognition. We have hitherto, indeed, obtained fragmentary glimpses of the man, partly from physicists, partly from physiologists; but his total merit has never yet been recognised as it assuredly would have been had he chosen a happier mode of publication."

3. If this be not sufficient, my error was one of ignorance, not of will; for it is an entirely new idea to me that Dr. Carpenter regarded his relationship to Dr. Mayer in the light of a "spontaneous abdication," and it explains to me, what I could not previously understand, the importance attached by Dr. Carpenter to the passages above quoted.

4. I have looked at p. 227, and, indeed, throughout the entire article in the *Medico-Chirurgical Review* (and elsewhere), for evidence to prove that "at that date" (or at any other date), Dr. Carpenter had "correctly apprehended Mayer's fundamental idea," which is that of quantitative or numerical equivalence. Had I found such evidence, it would give me sincere pleasure to reproduce it here, but my search for it has not been successful.

5. This however entirely depends on my ability to appreciate such evidence. Holding the opinion that he does regarding the claims of his work to public recognition, Dr. Carpenter is perfectly consistent in demanding that even in an after-dinner speech those claims shall not be ignored.

JOHN TYNDALL

THE GEOLOGY OF OXFORD*

PROFESSOR PHILLIPS'S new work on the Geology of Oxford and of the Thames Valley is a most important contribution to the knowledge of the ancient his-

tory of the earth, and supplies a need which happens just at this time to be keenly felt. The Palæozoic rocks had been described and the forms of life which they contain unfolded, in "Siluria." The second, or Mesozoic chapter, is written with remarkable ability in the present work.

FIG. 1.—Megalosaurus—hind leg. Scale, one-tenth of nature.

This restoration in outline of the left hind limb of Megalosaurus is drawn from specimens, with the exception of the fibula, calcaneum, and ordinary phalangeal bones—the claw-bone is known. Dotted lines represent the probable position of the pubic and ischial bones (according to the view of Professor Huxley); these being preserved in the British Museum and in the collections of the University of Oxford.

The principal bones are marked—il. = ilium, pub. = pubis, isch. = ischium, fem. = femur, tib. = tibia, fib. = fibula, c. = calcaneum, a. = astragalus. Cuvier supposed the calcaneum to be smaller than here represented.

The position of Oxford relatively to the formations which traverse Britain diagonally from the north-east to the south-west, equidistant on the one hand from the Malvern Hills which overlook the low-lying vale of Tewkesbury,

and on the other from the basin of the Lower Thames, renders it a convenient centre around which to group observations which are primarily local, but which also affect the general question of Mesozoic Geology. In its latter aspect the book demands a most careful attention. The large number of plates and the carefully prepared lists

* "Geology of Oxford and the Valley of the Thames." By John Phillips, M.A., F.R.S., F.G.S. (Oxford Clarendon Press: 1871).

FIG. 2.—Ilium of *Ceteosaurus*, seen on the external face. Scale, one-tenth of nature. *a b*. The acetabulum.

FIG. 3.—Scapulae of *Ceteosaurus*. Scale, one-tenth of nature

of fossils will be welcomed by all paleontologists ; and those who enjoyed the advantage of studying geology at Oxford will find in this book the subject-matter of many of the lectures, and will have recalled to their minds the

many pleasant associations connected with the expeditions of the Professor.

The work, as might be expected from the great and varied knowledge of the writer, is many-sided. In it the

physical geographer will find the delicate questions of denudation, and of the excavation of hill and valley, discussed; the meteorologist will find the rain-fall tabulated; the hydraulic engineer the amount of water which is available for the use of Oxford and of London; the

physicist the temperature and the prevailing winds; and the surveyor the position and thickness of the various strata from the Malverns eastward to London.

Prof. Phillips has, however, devoted his main strength to the description of the wondrous forms of reptilian life which

FIG. 4.—Femora and Fibula of *Ceteosaurus*. Scale, one-tenth.

The left-hand figure represents the specimen found in 1848; the right-hand figure that found in 1863; in the middle a small fibula found in 1848 is shown.

have been furnished by the neighbourhood of Oxford, and which are preserved in a museum which is worthy of an old and wealthy University. The description of the *Megalosaurus*, and especially of the *Ceteosaurus*, is a most valuable addition to Palaeozoology.

We owe to Prof. Huxley the clue to the right interpretation of the bones of both these animals, and the right definition of the whole group of *Deinosauria*, or *Ornithoskelida*, to which they belong, as being intermediate in character between the struthious birds and the reptiles. To this

conclusion, however, he was largely aided by Prof. Phillips, and that it is true is rendered almost certain by the independent observations of Prof. Cope on the fossil reptiles of America. When the large pelvic bone from

Stonesfield had been assigned to its true position in the skeleton of its possessor, and the so-called "clavicle" shown to be in all probability a long, stiliform, bird-like ischium, there could no longer be any doubt as to the

FIG. 5.—Head of *Megalosaurus*. Scale, one-tenth of nature.

Restoration of the head and lower jaw, of which, however, only the anterior portions are known. These are shaded. The type of *Varanus* is followed in general, but the postorbital arrangement is different, the bony circle there being completed from considering iguana and other lizards with some eye to crocodile. The length of head as thus drawn (thirty-nine inches) is less than that usually allowed (five feet). The posterior part of the maxillary bone is separated from the orbit, notwithstanding its smooth, apparently free edge, by an intervening continuation of the jugal. This may be objected to. The nasal cavity is supposed to be divided by a median ridge (the single nasal continuous with the intermaxillary bone) into two openings, as in some of the monitors. The intermaxillary bones, which originally included four teeth each, appear united to the maxillary in this adult specimen.

kind of animal to which it belongs. The massive anchylosed sacrum of five vertebrae, and the whole arrangement of the pelvic arch, as well as the peculiar form of

The specimens which are preserved in the Oxford Museum, and which have been figured by Prof. Phillips, afford a very complete idea of the creature. The magnificent upper maxillary described by Prof. Huxley in the "Geological Journal," enables the front portion of the cranium to be restored with considerable certainty, and the accompanying woodcut (Fig. 5) may be taken to represent the entire head.

The premaxillaries of the *Megalosaurus* from the Oxford clay, in the collection of Mr. James Parker, are traversed by foramina which may indicate the presence of a small horny beak, or snout.

The arrangement of the shoulder girdle may be seen in Fig. 6, in which 1 = Scapula; 2 = Coracoid; and 3 = Humerus, as well as that of the pelvic arch and hind leg (Fig. 1), and the comparison of the two diagrams, will show the enormous disproportion of the hind to the fore limb in respect of size. All these three figures are drawn to one-tenth of natural size, and enable us to realise the form of one of the most remarkable of the fossil reptiles. The recent discovery of a nearly perfect skeleton by Mr. James Parker establishes the fact that some, at least, of the opistho-coelian vertebrae, on which the genus *Streptospondylus* has been based by Prof. Owen, belong really to this animal. In point of time, the *Megalosaurus* lived from the Liassic to the Wealden age, and was one of the most formidable inhabitants of the great Mesozoic continent. The pains and labour which Prof. Phillips has bestowed in collecting and putting together the fragments and *dissecta membra* of the animal, and the careful criticism to which he has subjected each bone, render this portion of the work peculiarly valuable.

Nor is the chapter on the most gigantic of the fossil reptiles, the *Cetosaurus*, inferior in interest to that which relates to *Megalosaurus*. The bones discovered in the Great Oolite at Enslow Bridge, near Oxford, in 1870, settled for ever all doubt as to the animal having been aquatic or terrestrial. The scapula (Fig. 3) and the ilium (Fig. 2) resemble in general outline those of *Megalosaurus*, and show that the animal belongs to the

FIG. 6.—*Megalosaurus*. Scale, one-tenth of nature.

The left aspect of the shoulder girdle is here restored in outline from specimens in the Oxford Museum, which are complete except in regard to the lower end of the humerus. It will be remarked how bird-like in the general arrangement and the forms of the bones is the humero-scapular structure, and specially how closely it resembles *Apteryx*.

1. Scapula. 2. Coracoid. 3. Humerus.

the astragalus and the shape of the coracoid and scapula, indicate a close alliance with the birds; while, on the other hand, the rest of the structure is mainly reptilian.

same Deinosaurian class, although "its fore limbs are more crocodilian," and "its pelvic girdle more lacertian." And the evidence offered by the articular ends of the bones of the extremities being adapted for movement in particular directions, the possession of large claws, and the hollowness of the long bones, indicate that it was of terrestrial, and not, as its name seems to imply, of marine habit. It may, however, have been, as Prof. Phillips suggests, "a marsh-loving or river-side animal." Its gigantic size may be gathered from the fact that one of the femora measures no less than 64, and a humerus 51½ inches (Fig. 4).

Nor is there evidence wanting as to its diet. From the mutilated fragment of a tooth in the Oxford Museum, Prof. Phillips infers that its possessor lived on vegetables, since it resembled "that of an iguanodon in general shape (as far as can be known, one edge being broken), with a similar sweep of the concave surface seen in the diagram, and corresponding alternation towards the edge. The edge is not serrated, but the striae of accretion are so arranged as to suggest that it may have been." The truth of this conclusion is proved by the subsequent discovery of a nearly perfect crown by Mr. Burrows, one of my students, in the Enslow Quarry, which has very much the appearance of a young tooth. It presents the serrations which have been worn away in the specimen above described, and bears out completely Prof. Phillips's description.

I have chosen merely these two animals as illustrating the subject-matter of the book, which is in every sense worthy of the high reputation of its author. W. B. D.

PARTHENOGENESIS AMONG THE LEPIDOPTERA

THE part of the *Archives Néerlandaises*, published by the Société Hollandaise des Sciences à Harlem, for 1870, contains the results of some very interesting experiments undertaken by M. H. Weijenbergh, jun., on the above subject, one fraught with considerable interest to others besides entomologists. By Parthenogenesis is meant the power that is possessed by females of producing eggs endowed with vitality, and from which young ones are produced, without impregnation taking place on each occasion. This subject has been extensively treated by von Siebold in his "Wahre Parthenogenesis bei der Schmetterlinge und Bienen," Leipzig, 1856, but confirmatory and new investigations were much needed. Those of M. Weijenbergh were conducted with every possible care and precaution, so that they can be relied upon. In the autumn of 1866 he saw a male and female of the species *Liparis dispar* together, and some days afterwards he saw in the same place a great quantity of the eggs, about 500 in number. In order to leave the rearing of these to natural processes, as far as possible, he left them exposed all the winter in the open air, and in April 1867, he removed them into his house. Before the end of the month the caterpillars had successively made their appearance. These were regularly fed, and by the middle of July each of the chrysalides which had been formed during June gave birth to a perfect butterfly. It was easy, with a little practice, to distinguish the sexes whilst in the caterpillar state, and all the males were removed as far as possible, and the females were placed in a box closed to all access from without. So successfully was this separation of the sexes effected, that only one male butterfly made its appearance among the females; and, as these had been successively removed to a third closed box as soon as they escaped from the chrysalis state, it was only necessary to sacrifice the three or four females which were in the box at the time. In all, about sixty females were obtained, to which there was absolute certainty that no male could by any possible chance have had access. Of

these, two-thirds laid eggs in the autumn,—some, one, two, or three eggs only; others as many as ten or twenty, but yet even at the most not one-twentieth of the eggs of their mother. The other one-third laid no eggs at all. In all about 400 eggs were collected, which were removed and carefully packed up till April 1868, when a large number of little caterpillars were seen. These were immediately placed on leaves in a large glass vase and watched carefully. It was easily to be seen that this batch of caterpillars possessed far less vitality than those of the previous year. A large number of the eggs dried up and were worthless, some fifty caterpillars alone appearing, and of these only about forty survived to become chrysalides. From these, by the end of July, twenty-seven butterflies made their appearance. The same precautions having been taken as before, the number of females was found to be fourteen. Of these, when again there had been no possibility of male access, one half laid no eggs, the remaining half, however, laying in all a fair number. As in previous years, these were removed and left all the winter carefully packed up, till, in April 1869, three years after the commencement of the experiments, young caterpillars again made their appearance. From these, strange to say, the number of butterflies obtained was in excess of those obtained in the previous year. The number of females as compared with males, was almost the same, in contradiction to the results of other investigators, which had indicated the probability of the ratio of the males to the females greatly increasing with each additional year. The eggs laid by the females of this year, carefully isolated as before, were packed up during the winter, but when examined in the spring of last year, 1870, no caterpillars made their appearance, the eggs became shrivelled up, and the experiment was at an end. There is every reason to believe that it was most carefully conducted, and that every regard was paid to strict accuracy during the whole three years or more that the experiment was being carried on. The results amount to these:—

- (1.) Aug. 1866, eggs laid by impregnated female; April 1867, caterpillars appear; and, in July, perfect butterflies.
- (2.) Aug. 1867, eggs laid by females of this year without impregnation; April 1868, caterpillars appear, and, in July, perfect butterflies.
- (3.) Aug. 1868, eggs laid by females of this year without impregnation; April 1869, caterpillars appear, and, in July, perfect butterflies.
- (4.) Aug. 1869, eggs laid by females of this year without impregnation; April 1870, no results—the eggs all dried up.

Thus, after the first impregnation of the female in the autumn of 1866, three successive broods of caterpillars and, ultimately, of butterflies made their appearance; and four successive times were eggs laid without further impregnation, in three of which they proved endowed with vitality. It would take a long series of experiments, each conducted with the same care as this, before an average could be drawn to determine the limit of this strange reproductive power. These experiments are so easily performed, and yet so valuable when accurately made, that a wide field is opened to those who do not care to undertake long and elaborate scientific investigations, and to such we most cordially commend them. Their value, as bearing on the theories of spontaneous generation, is very great, as there is much apparent probability that this power of Parthenogenesis will increase as we descend in the scale of life just as it decreases as we ascend. By its aid many phenomena, now apparently very strange and perplexing, will be found to be but obeying one great and universal law of nature, which becomes less visible the higher we ascend in the scale of life, but yet never ceases.

In conclusion, it may be stated that this power of Parthenogenesis has been found in many species of butterflies, and also among bees; and M. Weijenbergh, at the

end of his interesting paper, gives a list of the seventeen or eighteen species which are known to him, or which are recorded as possessing this power. It is extremely probable that the more the subject is investigated, the more commonly will it be found to exist.

J. P. E.

RESULTS OF SANITARY IMPROVEMENT IN CALCUTTA.

WHEN a great public work is being done, it is a duty to call attention to it. In March 1862, Prof Longmore, of Netley, who had acted as Sanitary Officer during the Mutiny at Calcutta, gave the following evidence before the Royal Commission on the sanitary state of the Indian Army:—"As regards the chief part of this extensive city (Calcutta)—that inhabited by the native population—the pestilential condition of the surface-drains and yards, and many of the tanks among the huts and houses, would not be credited by any one who had not been among them." In the "Report on Sanitary Improvements in India up to June 1871," recently printed by the India Office, is given a table showing that the cholera mortality in Calcutta had, for twenty years preceding 1861, averaged nearly 5,000 deaths per annum. In 1860 the cholera deaths were 6,553, and in 1866 they were 6,823. About this latter date works of drainage and water supply were commenced and have been gradually extended. Water is taken from the Hooghly and thoroughly filtered—it is then conveyed in pipes $12\frac{1}{2}$ miles in length to a reservoir in Calcutta and thence distributed. The whole population had this benefit conferred on them in the beginning of 1870, from which date the use of foul tank and river water was discontinued.

The drainage works are as yet confined to the southern districts, the sewage from which is conveyed to an outfall at the Salt Lake, and will be passed over a square mile of reclaimed land there, for irrigation of crops. The mortality from cholera in 1870 was 1,563, and the general mortality has fallen year by year with the extension of the works. Last year (1870) the death-rate was $23\frac{1}{4}$ per 1,000, considerably less than half what it was in 1865.

At a Social Science meeting held in Calcutta last March, a native physician, Dr. Chuckerbutty, gave his experience of the sanitary results as follows:—"I am in the habit of visiting, in the pursuit of my profession, the houses of the rich, as well as of the poor, in both divisions of the town, and I frankly confess that in the southern division, wherever the drainage works have been brought into play, the dwellings even of the humblest cottagers are in an infinitely better sanitary state than the mansions of the richest millionaires in the northern division where the drainage operations have not been extended. Before the completion of the water-works and the partial operation of the new drainage works, the mortality in Calcutta from dysentery, cholera, and fever, was most appalling. In 1865 dysentery was so common and fatal that sloughing cases of it were of daily occurrence. Such cases are now rarely to be seen. My annual share of cases of cholera in the Medical College Hospital before the completion of the new water-works was about 700, and I declare to you that, during the last eight months, I have scarcely had a dozen cases of that disease. Fever, too, has decreased during the same period in a like manner." The actual deaths from cholera in April, May, and June, of the present year were 85, 29, and 26, respectively.

After such results as these, we need not feel surprised that the Justices of Calcutta, a large proportion of whom are enlightened native gentlemen, decided unanimously last August to extend the drainage works all over the city, notwithstanding the opposition on purely theoretical grounds of certain British medical officers who ought to have known better, to the use of ordinary house drainage for Indian houses.

The opinion of the Army Sanitary Commission on this

subject is quoted as follows in the India Office report:—"The municipal authorities of Calcutta and their officers have set an example of enlightened administration and effective expenditure to other Indian municipalities, which it is hoped will be followed. There are indeed few cities anywhere which can show so much good work done in so short a time and with such promising results for the future."

The laws of nature are the same everywhere. Calcutta has in times past suffered as London used to do from fatal fevers and bowel diseases, and there is now every prospect that a few years of active work will remove this stigma from the capital of the East, as it has been removed from the metropolis of the British Empire.

NOTES

THE following telegrams respecting the Total Eclipse of Dec. 12 have been received since our last:—"From the Governor of Ceylon to the Earl of Kimberley, dated, Colombo, Dec. 12, 10.45 A.M.:—"A telegram from Jaffna states that splendid weather prevailed during the eclipse. Most satisfactory and interesting observations have been made." "Mangalore, Dec. 16.—The eclipse observations have been very successful. The extension of the corona above hydrogen apparently small. Five admirable photographs have been taken." From Mr. Davis, photographer to the English Eclipse Expedition, through Lord Lindsay:—"Mangalore, Baikal.—Five totality negatives; extensive corona; persistent rifts; slight external changes." The French Academy of Sciences has received from M. Janssen the following telegraphic despatch, dated Octacmund, December 12, 5h. 20m.:—"Spectre de la Couronne attestant matière plus loin qu'atmosphère du Soleil."

WE can hardly credit the report which has just reached us that the Treasury has, at the last moment, declined to sanction the expenditure of public money on the publication of the Eclipse Reports of 1860 and 1870. We understand the combined report is now nearly ready, and both Parliament and the nation are entitled to receive a statement of the manner in which the public money has been expended. There are innumerable cases which may be cited as precedents for the publication of similar documents by the Government; as, for example, the Survey of Sinai, and the annual Greenwich Reports of Observations. After the Government has so generously granted money for recent scientific observations, we can hardly believe that the spirit of parsimony will so far prevail at the last moment as to mar, in this manner, the services it has performed towards Science.

THE death is announced on October 10, in Nicaragua, of fever, of Dr. Berthold Seemann, one of our most enterprising travellers and naturalists. Born at Hanover in 1825, Dr. Seemann was, in 1846, appointed naturalist to H.M.S. *Herald*, in its survey of the Pacific, during which voyage he had the opportunity of exploring, more thoroughly than almost any other European, the Pacific countries of South America and the Isthmus of Panama. In the same vessel he subsequently visited the Arctic regions, and the "Narrative of the Voyage of H.M.S. *Herald*," by Sir John Richardson and Dr. Seemann, is an important contribution to the natural history of previously little-known regions, the portion contributed by the latter comprising an account of the flora of Western Eskimo-land, north-western Mexico, the Isthmus of Panama, and the island of Hong-Kong. In 1860 he was sent by the English Government to the Fiji Islands, then lately acquired, and on his return published two works, one containing a narrative of his mission, the other, under the title of "*Flora Vitiensis*," a history of the vegetable productions of the islands. Since 1864, he has been greatly interested in the mining capabilities and other resources of the

various states of Central America, and has spent much of his time there in the interest of different trading communities, and in promoting the route across the Isthmus. Dr. Seemann is the author of several popular botanical works in German and English, and has been since its foundation, Editor of the *Journal of Botany, British and Foreign*.

PROF. SEDGWICK's appeal for subscriptions from members of the University of Cambridge, to enable him to purchase the valuable collection of fossils belonging to Mr. Leckenby, has resulted in the collection of the sum required, 800*l*. Arrangements have been made for the completion of the purchase, and it is expected that in a few weeks Mr. Leckenby's valuable collections will be deposited in the Cambridge Geological Museum. This prompt and liberal response to the touching appeal of the venerable Professor demonstrates the regard in which he is universally and deservedly held by the members of the University.

THE following is the result of the examination for the Natural Science Tripos at Cambridge:—First Class—Garrod, John's; Lydekker, Trinity; Lewis, Downing; Warrington, Caius. Second Class—W. Edmunds, John's; Fox, Peter's; Read, John's; Owen, Downing; Everard, Trinity; Maudslay, Trinity-hall; Brewer, John's; Buddon, John's; Wigan, Trinity; Blunt, John's. The following acquitted themselves so as to deserve ordinary degrees:—Burrows, Caius; Murphy, John's; Phelps, Sydney; Pittman, Corpus; Wakefield, Caius. In the second class Fox and Reed are bracketed, also Brewer, Buddon, and Wigan.

NEXT term, Mr. Ruskin, Slade Professor of the Fine Arts at Oxford, will deliver a course of lectures on "The Relation of Natural Science to Art."

THE Government is advertising the appointment, by open competition, of a clerk to the Curator of the Royal Gardens at Kew, and of a second assistant in the Herbarium. The salaries commence at 100*l*. and 60*l*. respectively, and the specified age is in one case from 20 to 30, and in the other from 18 to 30. The examinations will take place on January 16.

THE following lectures have already been delivered this winter at Manchester, as Science Lectures for the People:—The first on November 3 on "Yeast," by Prof. Huxley; November 10 "Coal Colours," by Prof. Roscoe; November 16, "The Origin of the English People," by Prof. A. S. Wilkins; November 24, "The Food of Plants," by Prof. Odling; December 1, "The Unconscious Action of the Brain," by Dr. Carpenter. These lectures are always well attended, but since they are all reported and printed at the low price of a penny each, they appeal to a much wider circle than most of a similar character. This is the third year of these Science Lectures. The lectures for this session and those of past years are published by John Heywood, Deansgate, Manchester.

THE *Pill Mall Gazette* states that the approaching 400th anniversary of the birth of Copernicus has revived a contest of long standing between Poland and Germany, each of which claims the great astronomer as a son. The Germans argue that he was a German because he was born in Thorn, which at the time of his birth was under German rule; to which the Poles reply that Thorn was then really a Polish town, having been separated from Poland only seven years before; that his father and mother were Poles; that when he studied at Padua he enrolled himself among the students of the Polish nationality; and that throughout his life he gave constant proofs of his attachment to Poland and her King. Poland has always honoured Copernicus as one of her greatest men. A statue of him was erected by national subscription many years ago at Warsaw, and there are two others at Cracow, besides which numerous Polish medals and books have been issued in celebration of his memory. The

anniversary above mentioned will be celebrated on the 19th of February, 1873, and great preparations are already being made at Posen for the occasion. The "Society of the Friends of Learning" in the old Polish city held a meeting the other day, at which it was decided, on the motion of a Polish clergyman, Canon Polkowski, to offer a prize for the best life of Copernicus, comprising the results of the latest investigations on the subject, and to publish it in the Polish, French, and German languages.

WITH a view towards the completion of the collection of water colour paintings illustrating the history of that art, Mr. William Smith, Vice-President of the National Portrait Gallery Trustees, has allowed Mr. Redgrave, R.A., the Inspector-General for Art, to select from his choice and valuable collection as many rare specimens as, in Mr. Redgrave's judgment, would illustrate the early period of the art. The works selected by Mr. Redgrave have been presented by Mr. Smith to the nation.

It has been arranged that the new machines for printing, composing, and distributing type, which have been recently perfected at the *Times* printing office, shall be completely exhibited in working at the London International Exhibition of 1872. The power of rapid production by these several means is probably threefold in advance of any existing modes of printing. The *Mail* newspaper will be printed three times a week, and if possible the daily supplement of the *Times*.

THE third part of Mr. W. H. Baily's "Figures of Characteristic British Fossils, with Descriptive Remarks," has just been published. Part 4, which will complete the first volume, is in progress; each part consists of ten beautifully-executed plates, and the text is interspersed with many woodcuts. These latter are chiefly of recent forms. The figures are for the most part original, and this little work most worthily fills up a blank in biological literature.

FROM the commencement of November till December 12, a period of six weeks, the temperature at London was below the average, with the break of only a single day. The tables forwarded weekly by Mr. Glaisher to the *Gardener's Chronicle* show the average depression during the whole of that period to have amounted to as much as 6°·5 F. below the mean of the last fifty years, the minimum being on December 8, when the thermometer fell to 18°·6, and the temperature of the twenty-four hours was 19°·3 below the mean. Throughout France the month of November was very severe, the mean temperature of the month having been lower only four times during the last century. According to statistics presented to the Academy of Sciences by M. Ch. Sainte-Claire Deville, the thermometer fell as low as -11°·3 C. (11°·7 F.) at Montargis on December 3, while even at Marseilles the remarkably low temperature (for that latitude) of -2°·5 C. (27°·5 F.) is recorded on November 23. During the present month the frost is stated to have been still more severe in France and Italy, where much snow has fallen at Rome; and the unusual depression appears to have extended to North America.

THE Smithsonian Report, 1869, contains an account of the eruption of the Volcano of Colima in June 1869, by Dr. Charles Sartorius. The height of the volcano is 11,745 feet, and it had remained in repose since the last eruption in 1818. On June 12, 1869, dense smoke issued from the crater, and violent detonations were heard. On the 13th smoke and stones were ejected from the crater, and a "glowing upheaval" of the surface was seen. It was visited on June 15, when it was found that an upheaval of some 114 feet by 754 feet had taken place, forming a flattened arch. The appearance was that of a wild mass of volcanic red-hot rocks heaped one upon another, and constantly in motion, not unlike freshly-burned lime when sprinkled with water. The rocks which rolled down were, on cooling, of a grey colour. A piece broken off rang like glass, and was vitreous and porous.

In the middle of the upheaved mass the movement was strongest; three large clefts and intense light were displayed, while engulfed stones, which were swallowed up in great masses, were followed by a noise as of violent wind, and by clouds of smoke sometimes blue, sometimes yellow. The temperature of the air in the vicinity was 126° F. The stones in the midst of the heaving mass seemed to be softened, though not melted, and no flow of lava took place. This upheaval had taken place on a small, flat plain upon the north-east side of the mountain, it ascended to the scarp of the cone, and stretched in the direction of the snow peak, which was some $2\frac{1}{2}$ miles distant. On reaching this summit the temperature was found to be 41° F. From here the whole of the new upheaval could be surveyed. In the middle of it the most vehement movement was in progress, attended by the constant upheaving and descent of rocky masses, fire, and blue and yellow columns of smoke. The upper ancient crater has a diameter of 492 feet, and from it arose dense sulphurous vapour. Later explorers found a fissure from the new upheaval to the upper peak, 1—3 feet wide and about 3 feet in depth, but neither heat nor vapour issuing from it. Such volumes of fetid gases issued from the fissure that the inhabitants of the district were forced to leave their abodes. Cows and sheep were killed by it, so that it was found necessary to drive away the herds from the neighbourhood of the volcano.

PROF. VERRILL has lately given, in the *American Journal of Science*, an account of the researches in marine zoology prosecuted by him during the past summer at Wood's Hole, Massachusetts, in connection with investigations of Prof. Baird respecting the food fishes of the coast of the United States; and in this he calls the attention of zoologists to some of the more important features of these examinations, promising a fuller account hereafter. One of these results consisted in ascertaining that, while the shores and shallow waters of the bays and sounds, as far as Cape Cod, are occupied chiefly by southern forms belonging to the Virginian fauna, the deeper channels and central parts of Long Island Sound, as far as Stonington, Connecticut, are inhabited almost exclusively by northern forms, or an extension of the Acadian fauna. Both the temperature observations at the surface and the deep-sea dredgings prove that there must be an offshoot of the arctic current settling into the middle of Vineyard Sound. Quite a number of interesting ascidians, both simple and compound, were met with by Prof. Verrill, several of them entirely new to science. Several new sponges were collected, and also a large number of crustaceans and molluscs previously unrecorded in that region. We would refer our readers to Prof. Verrill's article in the November number of the *American Journal of Science* for these interesting facts.

Harper's Weekly furnishes the following additional information of the great exploring expedition upon which Prof. Agassiz has been expecting to engage during the voyage of the Coast Survey steamer *Hassler*, from Boston to San Francisco, by way of the Straits of Magellan. The expedition was originally to start as early as July or August, and in that event the exploration in question would have commenced off the coast of the United States. Owing, however, to unexpected delays, the vessel has but recently fitted out and reported at Boston, where she has been detained, undergoing alterations of her machinery. We have already noticed the general plan and objects of the expedition. The scientific corps, as will be remembered, consists of Prof. and Mrs. Agassiz, Count Pourtales, ex-President Hüll, of Cambridge, Dr. White, Mr. James Blake, and Dr. Steindachner, each gentleman having special charge of a particular department of the work, and interested in its successful accomplishment. The vessel itself is under the command of Captain P. C. Johnson, with Messrs. Kennedy and Day as lieutenants. Owing to the lateness of the season, the original plan of making extended ex-

plorations in the West Indies and off the eastern coast of South America has necessarily been modified, and the vessel will probably proceed almost directly to the Falkland Islands and the Straits of Magellan, there to commence the comprehensive investigations proposed, as otherwise a sufficient share of the summer season of the Straits could not be secured. The Atlantic Ocean work thus given up will, in all probability, partly at least, be performed by the *A. D. Bache*, a consort of the *Hassler*, next year.

THE American Museum of Natural History, established at Central Park, New York, has, we learn from *Harper's Weekly*, had a most liberal offer made to it. The collection of shells of Dr. John C. Jay, formerly of New York, but now of Rye, is well known as one of the largest in the world; indeed, some years ago it was decidedly the finest in the United States; and although, with the lapse of years, the doctor has been less energetic in keeping it up to the present date, yet it forms a cabinet of magnificent extent, embracing, it is said, 14,000 species, 20,000 varieties, and 50,000 specimens, and costing many years of labour, and over 25,000 dols. in money. In addition to this, there is a library of 850 bound volumes, almost approaching completeness in its extent upon the subject of conchology. This has cost the doctor 10,000 dols., many of the works having been purchased at a time, too, when they were cheaper than at present. The doctor now offers to sell this library to the Museum of Natural History for the sum of 10,000 dols., and with it to present the entire collection of shells just referred to, so that the whole may go together, and form a complete section of the museum.

ADVICES from Portland, Oregon, under date of November 17, announce the arrival of Prof. O. C. Marsh, with his party of Yale College students, from an extended geological and palaeontological exploration in the Blue Mountains and the John Day Valley. As might have been anticipated from the previous discoveries of the Rev. Thomas Condon, of Portland, in the same region, under much less favourable auspices, very extensive collections of fossil animals were made, which, when placed, as intended, in the museum of Yale College with those previously gathered by Prof. Marsh, will make a series of the extinct vertebrates of North America unequalled in any other cabinet.

At the meeting of the Norfolk and Norwich Naturalists' Society, held Nov. 18, Mr. Barrett read some further notes on the coast insects found at Brandon, which he considered confirmatory of the opinion expressed by him in a former paper, that these species have occupied this district, now far inland, from the time when it was part of the sea-coast. Amongst other coast species mentioned by Mr. Barrett was *Agrostis Tyridici*, and of this species he remarked that, although it occurs sparingly on inland heaths, all the specimens are of a dull brown colour, whilst those found on the sea-coast are generally distinctly marked and richly coloured; all those taken by him at Brandon had precisely the deep style of colour and markings which characterise it on the sea-coast. *Agrostis cursoria*, although very abundant on the sea-coast, is not to be found at Brandon; and this Mr. Barrett considers a very strong proof that the other strictly littoral species enumerated have not reached their present situation by migrating across the intervening land from the present sea-coast. This species he thinks it not improbable was an immigrant from the eastward at a comparatively recent date, and that it has attained its greatest abundance on the spot where it first obtained a footing. It would not, therefore, have been an inhabitant of this portion of the post-glacial coast.

AN earthquake shock was felt in New Jersey, Delaware, and Pennsylvania in the United States, on October 9. At Delaware it was noticed at 9.40 A.M., and at Philadelphia at the same time.

THE MONOCOTYLEDON THE UNIVERSAL
TYPE OF SEEDS*

IT must be evident to those who heard my paper on "Adnation in Conifere" at the Chicago meeting of the Association that the observations there detailed could scarcely be accounted for, if the belief be true which is generally held by botanists, that the leaf originates at the node from which it seems to spring. It is not, however, an object with me to attack existing theories, or establish new ones, but simply to present facts as I see them. The origin of the leaf will no doubt prove a question which will in time take care of itself. But this generalisation cannot be avoided by the readers of that paper, that the whole plant is originally a unity; and that the subsequent formation of elementary organs, and their complete development, or absorption into one another, is the result of varying phases of nutrition. The leaves in Conifere were found to be free or united with the stem in proportion to the vigour of the central axis. Following up the subject, I now offer some facts which will show that all seeds are primarily monocotyledonous; and that division is a subsequent act, depending on circumstances which do not exist at the first commencement of the seed growth.

It is well known that in some species of Coniferous plants the number of cotyledons varies. I have noticed in addition to this that whether the cotyledons are few or many, there is no increase in the whole cotyledonous mass. In the Norway spruce, *Abies excelsa*, there are sometimes as many as ten cotyledons, in others only two. In the latter case they are broad and ovate, while in the former they are narrow and hair-like; in short, when in the two cotyledoned state it is not possible to note any difference between a seedling Norway spruce and a Chinese arbor vitae, *Biota orientalis*, except by the lighter shade of green. The two-leaved condition is not common, but specimens of threes and others I exhibited to Drs. Torrey and Gray at the Troy meeting. Any one who will examine sprouting seeds of the Norway spruce will agree to the proposition that the cotyledons are not original and separate creations, but a divided unity. My next observations were on some acorns of *Quercus agrifolia*, the division into cotyledons were numerous and irregular. Cut across vertically, some represented the letter C, others the letter N, and again, with four cotyledons the letter M. Here again it was clear that whatever the form and number of the cotyledons, there was no increase of the original cotyledon mass. Examining sprouting peach kernels, the variations in form and number were of the most remarkable character. I need not repeat them in detail here, as they are reported in the April and May "Proceedings of the Academy of Natural Sciences of Philadelphia." In addition to the fact of no increase in the whole cotyledon mass, it was here clear that when the cotyledons were duplicated, the duplications at least were subsequent to the original ones. Still so far nothing had been seen to indicate when the first pair of cotyledons were formed. *Quercus macrocarpa* and *Quercus palustris* were silent to my questions. In a large number I found no variations whatever. Each mass was divided smoothly and exactly into two cotyledons. *Quercus robur*, the English oak, however, gave some curious evidence. Two germs under one seed coat were numerous, and often three, and the cotyledons took on a variety of forms. But there was never any more increase in the cotyledonous mass than if but two lobes had been formed, and there was no more rule in the division than there would be in the sudden breakage of a piece of glass. A detailed account of these will also be found in the "Proceedings of the Academy of Natural Sciences of Philadelphia" for May. *Quercus rubra*, the American red oak, furnished the one link wanting to connect the first division into lobes with the other phenomena. All the acorns examined had three or four sutures in the cotyledon mass, and extending all along the longitudinal surface externally, without any reference to cotyledonal divisions. These sutures extended sometimes but a line in depth, at others almost to the centre of the mass, always accompanied by the inner membrane, as is the case in ruminated seeds. The whole mass was divided only in two parts in any that I examined of this species, but the division was always in the direction of the sutures. Hence each cotyledon was very irregular. Sometimes one-third the mass only went to one while the other had two-thirds of the whole mass. It was easier to burst in the weaker line of resistance. But the interest for us is to note that ordinarily the coty-

ledonous mass was a unit—then the sutures or fissures were formed, and ultimately the two divisions of the lobes followed in their direction. The division was the last condition, not the first. I know how much we should guard against generalising on a limited supply of facts, but it requires an effort to believe that oaks, pines, and peaches, as we have seen primarily monocotyledonous, are in this respect different from other so-called dicotyledonous plants; and if we grant that all seeds are primarily monocotyledonous, may we not ask why in any case they are divided? We have seen that there is no increase of mass in the division, the same amount is furnished in one as in many. Would it in any way injure the Indian corn to have its mass divided into two lobes? or would not the plantlet be as well provided for if the acorn were in one solid mass? Division would seem to be a necessity occurring subsequent to organisation, and existing from the position of the plumule alone. In monocotyledons, as we know, the plumule is directed parallel to, or away from, the cotyledonous mass, when, of course, on this theory, it remains an undivided mass. But in the dicotyledonous section, the plumule is directed towards the apex of the mass; and as we know in the case of roots against stone walls, or mushrooms under paving-stones, the disposition in the growing force of plants is to go right forward, turning neither to the right nor the left; so in this mass of matter the development of the germ would make easy work of the division; and no doubt often at so early a stage as to give the impression we have been under hitherto, that the division is a primary and essential process.

SCIENTIFIC SERIALS

THE *Monthly Microscopical Journal*, No. 35, November 1871. "On the Form and Use of the Facial Arches," by W. Parker, F.R.S., is chiefly occupied by observations on embryo salmon. "Another Hint on Selecting and Mounting Diatoms," by Capt. Fred. H. Lang, details the method employed by the author for remounting diatoms, either previously badly mounted, or from which it is desirable to select certain forms.—"The Monad's Place in Nature," by Metcalf Johnson, M.R.C.S.E., has for its object to show a connection between the earlier forms called Monads, and those higher and more complicated organisms at present recognised under the name of Infusoria, Mucedinæ, Conservæ, Oscillatorie, &c. The conclusions deduced from some of the experiments are that the author looks upon Monas in its earliest forms to be the starting point whence several products may result, and among the number are Infusoria, Mucedinæ, Englenæ, Oscillatorie. He is induced to believe that the Pin-point Monad, when developed under absence of light and only a limited quantity of air, gives rise to the class of plants known as Mucedinæ. Again, he maintains that during the watching of the liquids under experiment the Monads presented various forms, evidently transitional, from the round Pin-head Monad to oval young Paramœcia, until we come to sufficient size to give it a name such as *Kolpoda cucullus*, &c.—"Infusorial Circuit of Generations," by Theod. C. Hilgard, deals with a similar subject, but in a very different style. It is often very difficult to gather the author's meaning from language such as the following:—"And from each little dot in these 'clouds of life' a separate vorticella can be seen to develop! It is here, indeed, at this first visible advent or exordium of animate life, and the resurrection of millions of germs through the spontaneous dissolution of a single one, that the last tubercular microscopic perceptions closely resemble the last nebular telescopic as well as the *theoretic* ones of Laplace's cosmogony." The concluding portion of this paper, which is reprinted from *Silliman's Journal*, appears in the succeeding number, and is interesting as a contribution to the "curiosities of scientific literature."

THE *Monthly Microscopical Journal*, No. 36, December 1871.—"Notes of Prof. James Clark's Flagellate Infusoria, with Descriptions of New Species," by W. Saville Kent, F.Z.S. An entirely technical paper, consisting of the diagnostic characters of new species, with those of previously-described ones amended. Eleven forms are figured and described, all of which were found in fresh water at Stoke Newington.—"On Bog Mosses," by R. Braithwaite, M.D., F.L.S., Part II., is occupied chiefly with the anatomy of the leaf and development of the plant.—"On the Conjugation of Amœba," by J. G. Tatem, is a note serving to strengthen the supposition previously advanced by this author, "that these large Amœbæ so frequently met with in the autumn months are actually the incorporation of two individuals in a

* Abstract of a Paper read at the Indianapolis Meeting of the American Association for the Advancement of Science, August 1871, reprinted from the *American Naturalist*. By Thomas Meehan.

copulative act," from which free-swimming ciliated germs might eventually issue. "On the Connection of Nerves and Chronoblasts," by M. Georges Pouchet. The inference drawn from an examination of the pectoral fin of a young flat-fish is that there is a reality of connection between the nervous and sarcoid elements, but that the nature of this connection is unknown.

Tiite Keine Scientifique, Nos. 19-25, contains, among others, the following articles, translations, and reprints:—General Morin's eulogy on Piobert and his inventions in artillery; Dr. Carpenter's lectures at the Royal Institution; the continuation of Grehant's course of lectures on Experimental Physiology; M. Lorain on primary and secondary instruction in France; Berthelot on the union of alcohols with bases, and on the history of carbon; Moleschoit on the regulators of human life; Sausure on the life and works of Claparède; Valentin on the electric properties of nerves during embryonic life, and during putrid decomposition; a summary of the most important papers read at the Bologna International Congress of Anthropology and Prehistoric Archaeology; Contejan on the origin of sedimentary deposits; Mr. Benthams last anniversary address to the Linnean Society; Fonvielle on aerial navigation; Prof. Huxley's article in the *Contemporary Review* on English Critics of Darwin.

THE twentieth volume (1870) of the *Verhandlungen der k.k. zoologisch-botanischen Gesellschaft in Wien*, although a stout octavo, is hardly equal in bulk or in the variety of its contents to some of its predecessors; nevertheless its readers will find in it an abundant supply of valuable papers on zoological and botanical subjects. As usual, entomological articles are in the majority under the former head, and here Dr. Winnertz leads off with two papers on Diptera, containing descriptions of species belonging to the *Leptotritinae*, a sub-family of Cecidomyiidae, and of the species of *Heteropeza* and *Mastor*—two genera of the same family. Singularly enough these, and a short notice by M. von Bergenstamm on the metamorphoses of *Platyphaca holoserica*, are the only papers on Diptera in the volume.—The Lepidoptera also receive but little notice, but on the Rhynchota we have some important papers.—M. P. M. V. Gredler furnishes a list, with notes, of the Heteropterous Rhynchota of the Tyrol, and Dr. F. N. Fieber the characters of twelve new genera and twelve new species of the same group. The forms described by the latter are from various parts of Southern Europe.—M. C. Tschek describes a number of Austrian Ichneumonidae belonging to the group of the Cryptoides, Dr. G. Mayr a number of new species of ants, and Dr. J. Kriechbaumer four new South European species of humble bees.—A paper on the Orthoptera of the Syrmian valley in Hungary by M. V. Graber, which includes an interesting description of the district, is the only other entomological paper to which we shall refer.—The malacologist will find a list of the land and freshwater mollusca of Galicia by Dr. J. Jachno, a monograph of the genera *Emmerida* and *Fossaridius* by M. Brusina, and an important paper on the anatomy of *Trilophophorus* and *Philomyces*—two forms of naked Pulmonata; whilst for the ichthyologist we have the first part of a descriptive synopsis of the fishes of the Red Sea from Dr. C. B. Kluwinger, who also notices the animals observed upon a coral reef in the Red Sea.—M. D. Dybowski describes a new form of Salamander from Siberia under the name of *Salamandrella Keyserlingii*, and Dr. Burmeister gives a description of the pelvis of *Megatherium*. The botanical papers are to a considerable extent of the nature of local lists, but some of these contain a good deal of descriptive matter. Thus in M. Schulzer von Muggenburger's "Mycological Observations in North Hungary" we find many descriptions of fungi; Glowacki and Arnold's "Lichens from Carniola" contains descriptions of species, as does also the latter's "Lichenological Excursion into the Tyrol," and the contribution to the moss-flora of East by M. M. Juratzka and Milde. M. F. Hanzlinsky describes the *Sphaeria* which are parasitic upon the rose; M. Julius Klein's mycological communications contain a description of a new genus of Mucorine fungi, and of some other forms which grew with its representative; and M. Schulzer von Muggenburger, above-mentioned, has also his mycological contributions, which consist almost entirely of descriptive matter. The papers which treat of the higher forms of plants, and those describing the natural history journeys of their authors, are not numerous. We may mention especially a long paper by M. F. Krasan on the periodical phenomena of vegetable life, and an article by Dr. A. Unterhuber on the position of the scales of the fruit in *Ceratostema mexicana*. This list of papers will be sufficient to show how much there is in the proceedings of the Vienna Zoologico-Botanical Society to interest both the zoologist and the botanist.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, December 6.—Mr. J. Prestwich, president, in the chair. Prof. Giovanni Capellini, of Bologna, was elected a Foreign Correspondent of the Society. 1. "On the presence of a raised beach on Portsdown Hill, near Portsmouth, and on the occurrence of a Flint Implement at Downton." By Mr. Joseph Prestwich, F.R.S., President. The author noticed a section observed by him in a pit ten miles westward of Bourne Common and five miles inland in a line on the north side of East Cams Wood. It is situated at an elevation of 300 feet above the sea level, and shows some laminated sands with seams of shingle, overlying coarse flint-shingle with a few whole flints, which the author regarded as a westward continuation of the old sea-beach which has been traced from Brighton, past Chichester, to Bourne Common. A flint flake was found by the author at the bottom of the superficial soil in this pit. The author also noticed the occurrence of a flint implement of the type of those of St. Acheul in a gravel near Downton in Hampshire. This gravel capped a small chalk-pit, and its elevation above the River Avon was about 150 feet. Two gravel terraces occur between this pit and the river, one 40 by 60 the other 80 by 110 feet above the level of the latter. Mr. Coddington stated that, according to the Ordnance Survey, the level of the pit at Cams Wood was not more than 100 feet above the sea, so that it was at about the same level as the gravels of Titchfield and elsewhere. Mr. Evans remarked that the flint flake from Cams Wood presented no characters such as would prove it to be of Palaeolithic age. He was, on the contrary, inclined to regard it as having been derived from the surface. He commented on the height at which the Downton implement had been discovered, which was, however, not so great but that the containing gravels might be of fluvialite origin. Mr. Gwyn Jeffreys thought that if the beds at Cams Wood were marine, some testaceous remains might be found in them. If these were absent, he should rather be inclined to regard them as fluvialite. Mr. J. W. Flower contended that the gravel at Downton could not be of fluvialite origin. He thought, indeed, that the gravel was actually at a higher level than the present source of the river. If this were so, he maintained that the transport of the gravel by fluvialite action was impossible. He further observed that gravels precisely similar, also containing implements, had now been found, as well in the Hampshire area as elsewhere, the transport of which, in his view, could not possibly be attributed to any existing rivers. At Southampton they occur 150 feet above the River Itchen and the sea, and considerably inland; at Bournemouth, on a sea cliff 120 feet in height; and at the Foreland (at the eastern extremity of the Isle of Wight), on a cliff 82 feet above the sea, and far remote from any river. If, therefore, these deposits were effected by fluvialite agency, it was evident that all traces of the rivers were afterwards effaced by some great geological changes, or, in the alternative, some great geological change, not fluvialite, must have caused the deposit. Upon the whole he was disposed to conclude with the French geologists as well as with many eminent English authors that the accumulation of all these superficial drifts was, as the late Sir Roderick Murchison had said, sudden and tumultuous, not of long continuance; and thus it was such as would result from some kind of diluvial action, rather than from the ordinary long-continued action of water. Mr. Judd pointed out, in contravention to Mr. Jeffreys' views, that in the Fen district, over large tracts of deposits of undoubtedly marine origin, not a trace of marine shells could be found. Mr. Prestwich, while willing to concede that the implement-bearing gravel-beds had been deposited under more tumultuous action than that due to rivers of the present day, was still forced to attribute the excavation of the existing valleys and the formation of terraces along their slopes to river-action. He showed that Mr. Flower's argument as to the present level of the source of the river was of no weight, as the country in which it had its source was formerly, as now, at a much higher level than the gravel at Downton. As to the absence of marine shells at Cams Wood, he cited a raised beach in Cornwall which, in company with Mr. Jeffreys, he had examined for a mile without finding a trace of a shell, though for the next half-mile they abounded. There was the same difference between the raised beach at Brighton and at Chichester. He was obliged to Mr. Coddington for his correction as to the level at Cams Wood, though the pit was at a higher elevation than the one to which Mr. Coddington had alluded.—2. "On some undescribed Fossils from the 'Menevian Group of Wales.'" By Mr. H. Hicks. In

this communication the author gave descriptions of all the fossils hitherto undescribed from the Menveian rocks of Wales. The additions made to the fauna of the Lower Cambrian rocks (Longmynd and Menveian groups) by the author's researches in Wales during the last few years now number about fifty species, belonging to twenty-two genera, as follows:—Trilobites, 10 genera and 30 species; Bivalved and other Crustaceans, 3 genera and 4 species; Brachiopods, 4 genera and 6 species; Pteropods, 3 genera and 6 species; Sponges, 1 genus and 4 species; Cystidians, 1 genus and 1 species. By adding to these the Annelids, which are plentiful also in these rocks, we get seven great groups represented in this fauna, the earliest known at present in this country. By referring to the Tables published in M. Barrande's excellent new work on Trilobites, it will be seen that this country also has produced a greater variety, or, rather, representatives of a greater number of groups from these early rocks than any other country. The species described included *Agnostus*, 5 species; *Arionellus*, 1 species; *Eriopus*, 1 species; *Holoccephalus*, 1 species; *Conocoryphe*, 2 species; *Anololemus*, 2 species; *Cyrtotheca*, 1 species; *Stenotheca*, 1 species; *Theca*, 2 species; *Protocystites*, 1 species, &c. The author also entered into a consideration of the range of the genera and species in these early rocks, and showed that, with the exception of the Brachiopods, Sponges, and the smaller Crustacea, the range was very limited. A description of the various beds forming the Cambrian rocks of St. David's was also given, and proofs adduced to show that frequent oscillations of the sea-bottom took place at this early period, and that the barrenness of some portions of the strata, and the richness of other parts, were mainly attributable to these frequent changes. Mr. Gwyn Jeffreys suggested that the term Polyzoa might be adopted in preference to that of Bryozoa, as being the more ancient term, and that the name *Proserpina* should not be applied to the new genus of Trilobites, as it had already been appropriated to a tropical form of land-shell.

Royal Geographical Society, December 11.—Major-Gen. Sir H. C. Rawlinson, president, in the chair.—A paper was read by Mr. Keith Johnston, "On the Rev. Thomas Wakefield's Map of Eastern Africa;" the subject being limited to the form of Speke's Lake Victoria Nyanza, which Wakefield's native travellers had decided to consist of at least two lakes.—Capt. R. F. Burton followed with a paper on "Lake Ukara or Ukaru," in which he argued from the new information gleaned by Mr. Wakefield at Mombaz, and Captain Speke's own data, that Victoria Nyanza consisted of many separate lakes, and that it was a "Lake Region," and not a single lake.

Sunday Lecture Society, December 17.—"On the Optical Construction of the Eye," by Dr. Dudgeon. The early part of the lecture was occupied with a description of the optical construction of the eye. In order to ascertain the precise focal length of aqueous humour, the lecturer immersed his eyes in water, which, being of the same refractive power as the aqueous humour, extinguishes it as a lens. He then ascertained what power of lens was required to restore perfect vision under water, which he found to be affected by an artificial lens, whose focus was exactly $1\frac{1}{2}$ inch under water. He constructed a pair of spectacles fitted with air lenses, formed by very concave watch-glasses placed back to back, and united round their edges by a ring of wood or vulcanite. In this way he formed air lenses which had a focus of $1\frac{1}{2}$ inch in water, but which offered no obstruction to vision in the air. With these spectacles perfect vision both for near and distant objects below the water was obtained, and on coming to the surface these spectacles allowed of perfect vision in the air. He then explained the construction of the eyes of fishes and amphibia, which have no anterior aqueous lens, but only a nearly spherical crystalline lens. He next explained the mechanism of the accommodation of the eye from distant to near vision. He showed that this was not effected by any increase of the convexity of the anterior surface of the crystalline lens, as is generally supposed, but by a slight rotation of the crystalline lens from without inwards, whereby the focus of the crystalline lens was shortened to the degree necessary to throw the image of a near object accurately on the retina. Finally, he pointed out that some of the principal discoveries of modern physicists already existed in the eye. Thus, the principle of achromatic lenses by the combination of two lenses of different refractive power was seen in the eye when a water lens was combined with the crystalline lens; the discovery of Descartes, that an elliptical surface of a lens obviated spherical aberration, was also found in the eye; and Herschel's discovery that a combination of the meniscus with the double

convex lens prevented spherical aberration also obtained in the eye.

Photographic Society, December 12.—A paper was read by Lieut. Abney, R.E., F.R.A.S., on albumen applied to photography. He first referred to the use of albumen as a substratum for collodion films. Taking different proportions of albumen and water, and iodising part of each, he found that with the best collodion process the iodised substratum as a whole gave neither increase nor diminution of sensitiveness, whilst with the uniodised substratum the sensitiveness was slightly diminished. He next pointed out the cause of blisters in developing dry plates, and traced them to the expansion of the albumen; the substratum rising from the glass at the smoother portions. He lastly touched upon the uncombined sulphur always present in albumen, as much as $1\frac{1}{2}$ grains being found in a whole sheet of paper, whilst but $\frac{1}{2}$ grain of metallic silver was found in prints of the same area. He argued from this that silver prints must fade, apart from the imperfect washing, unless the sulphur be removed. He recommended the makers of albumenised paper to try to do this, first forming albumenate of potash by the addition of potash to the albumen. The unprecipitated part contained the sulphur. This might be removed and the albumen once more dissolved by the addition of acid.—A paper on M. Dagron's microphotographic despatches was also read, detailing the methods of preparation; as many as 50,000 messages were received in Paris during the Siege upon these films, conveyed to the capital by pigeons.

MANCHESTER

Literary and Philosophical Society, November 14.—E. W. Binney, F.R.S., president, in the chair. The president said that, on Friday the 10th inst., he observed at Douglas in the Isle of Man, a splendid display of the aurora borealis. At 8 p.m. it appeared as an arch of a greenish colour, extending from west to east, through the tail of the Great Bear. Afterwards, at ten o'clock, the same kind of arch was observed with another higher up, which ranged west and east through the Pole star. At this time numerous streamers and flashes of light of a green and yellowish-white colour flashed up from near the horizon to the zenith, from east, south, and west; those towards the west had a reddish hue. The sky was beautifully clear, and the light from the aurora was greater than ever previously observed by him.—"On the Origin of our Domestic Breeds of Cattle," by William Boyd Dawkins, F.R.S. There are at the present time three well-marked forms inhabiting Great Britain. 1. The hornless cattle, which have lost the horns which their ancestors possessed through the selection of the breeder. The polled Galloway cattle, for instance, are the result of the care taken by the grandfather of the present Earl of Selkirk, in only breeding from bulls with the shortest horns. The hornless is altogether an artificial form, and may be developed in any breed. 2. The *Bos longifrons*, or the small black or dark brown Welsh and Scotch cattle, which are remarkable for their short horns and the delicacy of their build. 3. The red and white variegated cattle, descended from the urus, and which have on the whole far larger horns. These two breed freely together, and consequently it is difficult to refer some strains to their exact parentage. The large domestic cattle of the urus type are represented in their ancient purity by the Chillingham wild oxen, as they are generally termed, but the exact agreement of their colour with that specified in the laws of Howel Dha proves that they are descended from an ancient cream-coloured domestic ox with red ears. The animal was introduced by the English invaders of Roman Britain, and was unknown in our country during the Roman occupation. The *Bos longifrons*, on the other hand, was the sole ox which was domestic in Britain during the Roman occupation, and in the remote times out of the reach of history it was kept in herds by the users of bronze, and before that by the users of polished stone. This is proved conclusively by the accumulations of bones in the dwelling-places and the tombs of those long-forgotten races of men. The present distribution of the two breeds agrees almost exactly with the areas occupied by the Celtic population and the German or Teutonic invaders. The larger or domestic urus extends throughout the low and fertile country, and indeed through all the regions which were occupied by Angle, Jute, Saxon, or Dane; while the smaller *Bos longifrons* is to be found only in those broken and rugged regions in which the unhappy Roman provincials were able to make a stand against their ruthless enemies. The distribution, therefore, of the two animals corroborates the truth of the view taken by Mr. Freeman, that the conquest of Britain by the

English was not a mere invasion of one race by another, but as complete a dispossession as could possibly be imagined. The *Bos longifrons* lingers in Wales, after having once occupied the whole country, just as its Celtic owners still linger, while the urus is an invader just in the same sense as their English possessors. The *Bos longifrons* is of a stock foreign to Europe, and the urus was most probably domesticated in some other region by those Neolithic people. Both these animals have probably been derived from an area to the south-east of Europe, and were introduced by the Neolithic herdsmen and farmers at a very remote period.

DUBLIN

Royal Dublin Society, November 20.—Prof. R. Ball, M.A., in the chair. Mr. Maurice Cole exhibited and explained a working model of an improved seed sowing machine.—Prof. Edward Hull, F.R.S., read some notes of a recent visit to Vesuvius.—Dr. Emerson Reynolds exhibited a new apparatus for gas analysis, and Mr. A. G. More exhibited some specimens of well-stuffed birds from the museum of the Society.

Royal Irish Academy, November 30.—Rev. J. H. Jellett, president, in the chair. The Secretary read a paper by M. Donovan on Earl Stanhope's alleged imperfections of the tuning fork; also for Dr. Whitley Stokes a paper on a fragment of Cornac's glossary.—Mr. G. H. Kinsland read a paper on and exhibited sketches of what appeared to him a new type of Clochan, observed in the county of Mayo, South of Louisburgh. The structure was composed of large flugs inclining inwards to form sloping sides and roof, the very apex of which was covered by horizontal flags. He also exhibited a sketch of a form of cross observed in the same neighbourhood, and which was unlike anything he had ever seen.

PARIS

Academy of Sciences, December 11.—M. J. Boussingault read a paper on a remarkable property of the points where the lines of greatest slope of a surface have their osculatory planes vertical, and on the difference which generally exists at the surface of the earth between the lines of the ridge or the thalweg, and those along which the slope of the soil is a minimum.—M. Bequerel presented a third memoir on the discoloration of flowers by electricity, and on the cause of the phenomenon, in which he shows that electricity acts in this case by destroying the envelopes of the cells containing the coloured materials. Heat produces the same effect. The author remarked upon some general applications of these facts.—A paper on the diffusion and deleterious influence of mercurial vapours, by M. Merget, was read. The author disputed the conclusions of Faraday, founding his opposition upon experiments and observations which show that the vapourisation of mercury is a continuous phenomenon not even interrupted by the solidification of the metal, and that the vapours emitted by it are capable of great diffusion, nearly in accordance with the dynamic theory of gases. M. Dumas called attention to some observations on this subject by M. Boussingault.—M. C. A. Valsen presented a note on the part played by space in the phenomena of solution, in which he discussed the contraction produced by the solution of various salts in water.—A note on different acoustic phenomena observed during balloon-ascent, by M. W. de Fonville, was read. The author remarked upon the fact that certain acute but very feeble sounds are often heard in balloon ascents, and accounts for the phenomenon by the reverberation of the balloon itself.—M. Serret presented a note by M. de Tastes on a new propeller, consisting of a plate or fan worked in the manner of the tail of a fish or whale.—M. A. Barthélemy presented a memoir on the vibrations communicated to mercury and liquids in general, in which he described and figured the curious effects produced by these vibrations in vessels of various forms.—M. Delaunay read a note on the cold of the 9th December, containing some interesting observations on the range of this extreme cold over the Continent of Europe; and M. C. Sainte-Claire Deville presented a second note on the precocity of the cold in the present year.—M. P. P. Dehérain presented a memoir on the intervention of the nitrogen of the atmosphere in vegetation, in which he demonstrated by experiment the absorption of the atmospheric nitrogen by decomposing organic matters, and suggested that by this means nitrogen may be absorbed by the soil.—M. Wurtz presented a note by MM. C. Friedel and R. D. Silva, on the action of chlorine upon chloride of isopropyl; and a note by M. E. Grimaux on derivatives of chloride of tolylene.—A note was read by M. Dubrunfaut on the combustibility of carbon, in which he maintains that carbon

is combustible only in gases containing water; and another by M. F. Jean on the quantitative determination of glucose, recommending a process depending on the precipitation of metallic silver by prochloride of copper, prepared from the protoxide precipitated by glucose.—The deposits of phosphate of lime in France formed the subject of three papers, namely, a note on the composition of that recently worked in the Departments of Tarn-et-Garonne and of the Lot, by M. A. Bobière; an account of the deposits of Saint-Antonin and Caylux, in the former department, by M. Trutat; and a short note on the organic origin of the deposits in the Quercy, by M. Malinowski. M. Trutat described the structure of the deposits, and noticed the remains of certain mammalia found in them.—M. Daubrée communicated a note by M. P. Fischer on the existence of Lower Tertiary strata in Madagascar. These beds, belonging apparently to the great Nummulitic formation, occur on the west and south-west coast of the island. No nummulites have been found in them.—M. E. Blanchard presented a note by M. A. Milne-Edwards on the structure of the placenta in the Tamandua. The author describes this placenta as differing in various respects from those of other Edentata, and remarked that the diversity in the fetal envelopes of those mammals would lead to the supposition that either the characters derived from them are not so important among the Edentata as in other groups, or the forms united in the Edentata are less nearly related than is generally supposed. He is inclined to the latter opinion.—M. Duchartre communicated a note by M. J. de Seynes on *Pentellium bicolor*, Fr.; and M. Robin presented a note by M. Rabuteau on the physiological properties of various chlorides.

BOOKS RECEIVED

ENGLISH.—Nature; or, the Poetry of Earth and Sea: From the French of Madame Michelet (E. Nelson and Sons).—The Mountain: From the French of J. Michelet (T. Nelson and Sons).—Beautiful Birds in Far-off Lands: M. and E. Kirby (T. Nelson and Sons).—Text Books of Science: Theory of Heat: J. Clerk Maxwell (Longmans).—A Manual of Zoology: H. A. Nicholson: and ed. 2nd (Blackwood).—Comparative Metaphysics: Part II.: S. H. Hennell (Trübner).

TECHNICAL EDUCATION IN HOUSE
CONSTRUCTION

REFERRING to the recent sad events at Lonsborough Lodge, and the disclosures made in the medical press, showing how the whole internal air of this house was tainted with sewer gas for want of ordinary care, the *Times*, in an able article which appeared on December 9, has the following telling passage: "What a satire on the universal diffusion of knowledge, on the lectures of the Royal Society, on hundreds of scientific and educational institutions, and all our new inventions and discoveries! Here is the simplest thing in the whole world, which wanted only common sense, and nobody seems to have thought of it—nay, we are not sure that our architects and builders will be thinking of it next year. It is far too simple and too deadly an affair."

We purpose to deal with this subject; and in doing so to show briefly how it is that with every apparent advantage our houses are still not altogether safe to live in.

In the first place, the whole subject of house-drainage has been thoroughly discussed, and simple rules have been laid down, which any one with ordinary technical skill can apply to any conceivable case.

The question has been treated in published reports by the Health of Towns' Commission, by the Metropolitan Sanitary Commission, by the General Board of Health, by the Barrack and Hospital Improvement Commission, by the Local Government Act Office, and recently, by the Army Sanitary Commission, for application in India. These official documents, extending over a period of nearly thirty years, contain all the principles on which wholesome house-conveniences can be constructed; and besides all this, engineering, architectural, and medical journals have never ceased to advocate attention to the requirements of healthy house construction. The Legislature, on its side, has been anxiously engaged in defining and granting every necessary power for the efficient carrying out of town-drainage works; but hitherto these powers have stopped short with the house drain. All between the head of the house drain and the interior of our bedrooms has been left to chance, or to the imperfect knowledge or no knowledge of such officials as we have seen defending the deadly arrangements of existing houses, or to plumbers' journeymen or apprentices. The whole experience shows that every official has considered his duty fulfilled when he had ensured an outlet for the refuse water of the house. As to the subsidiary traps, and such like things, they have been introduced without regard to scientific considerations; so that, instead of proving an advantage, they have, in some instances, increased the evil. Now, it must henceforth be recognised that house drainage is not a question of hydraulics merely, it is in a higher sense a question of pneumatics; but even in this extended sense it is far from being a difficult art, as some would have us suppose. It is by no means a "refuge of despair," as some have asserted. It is a great and beneficial necessity. Because carelessly-fitted water-pipes are burst by frost, and our houses are deluged every

winter, are we to have a crusade against water supply? Bursting of water-pipes and the influx of foul air from sewers are indications of want of ordinary common sense; or, at all events, of very ordinary technical skill. And the real future question before us, is not whether we are to abolish household drainage and water supply, but whether some public control in these matters ought not to be exercised over the proceedings of plumbers' apprentices and other similar persons, so that when we rent or buy a house, we may be assured that typhoid fever, or some other pestilence, is not included in the contract. Every such contract should, however, ensure three things, viz., that water-pipes are protected from frost; that the house is thoroughly drained; and that no sewer-air can, under any circumstances, enter the house. Now all these things can be assured.

It is a mere truism to say that there are plenty of non-conductors of heat with which water-pipes can be efficiently surrounded. Why should water-pipes be left uncovered under flooring or in walls, as at present? Surely any local authority could deal with so simple, and, at the same time, so important a question as this.

As regards efficient drainage-pipes, traps, and the like, there are great manufacturing interests involved in the production of these, and any one who will cast an eye over the advertising columns of our architectural and engineering contemporaries, will see how much ingenuity and wholesome competition there exists in the production of the most scientific forms of apparatus of this class. But the missing link in the whole of these drainage arrangements is how to prevent foul air entering the house. In an ordinary second or third-class house in London, there are three or four water-closets, the main pipe from which enters the drain, either directly or through an inefficient trap. It may be safely stated that at all times there is more or less pressure of sewer air on the pan or trap of the closet, which must lead to an infiltration of foul air into the house. But nobody appears to have applied the long-known remedy for this, viz., to take off the pressure by a small leaden pipe carried from the upper end of the soil-pipe to the open air.

It is not, however, from the soil-pipe that most of the danger arises. Houses of the same classes have generally what is called a safe under the water-closet, from which safe a pipe passes directly to the drain. Next there may be a bath with its outlet pipe, its overflow, and the pipe of its safe, all connected with the drain. There may be three or even four sinks all connected with the drain, and then every cistern has its overflow, also connected with the drain. As these various open pipes are distributed all over the house, we can easily understand how, while fulfilling the function of removing waste water, they may, in conformity with the laws of pneumatics, distribute the most deadly poison among the unconscious sleeping inmates of every bed-room.

Foul sewer air returns into a house for the following reasons, viz.:—1. A wind-pressure exercised on the open mouth of a sewer perhaps many miles away; or a similar pressure exerted on an ordinary gully grate. 2. By pressure of foul air into the house from the superior specific gravity of the atmosphere outside. 3. The draft of chimneys, when doors and windows are shut, as during the night. This draft must be supplied, and will supply

itself from every one of these small pipes, perhaps a dozen or more in a house, if it cannot be supplied more easily elsewhere.

The principles to be kept in view in dealing with defects such as those stated are obvious enough.

The general drain system of every street or district should be studied as regards its pneumatic relations, and means should be adopted for relieving the pressure within the system by ventilating outlets in safe positions. By placing charcoal strainers at all these outlets, sewer air would be deprived of its destructive qualities before passing into the streets. In special cases provision would have to be made for preventing the tide or strong winds from entering the mouth of the main sewer.

Then as regards the household drains. There is nothing easier than to ventilate the soil-pipes through charcoal filters in the manner stated. And as regards the numerous small pipes of sinks, baths, &c., not one of these ought on any account to communicate directly with a sewer. They ought all to be collected and allowed to discharge their contents in the open air over a trap communicating with the house drain, so that reflux of sewer gas into the house would be simply impossible.

Much evil has in times past arisen from imperfect drains within houses. Properly there should be none such. All connections of water-closets, sinks, baths, &c., with the house drain, should take place outside the house walls, and where from bad construction drains have been laid within houses and cannot be altered, they should be replaced by glazed earthen pipes laid in concrete, every joint made perfectly air-tight.

Cess-pits and traps ought never to be permitted within walls. The trapping should be all outside.

From want of attention to these long-known principles most of our houses are sick, and require separate diagnosis and treatment. They can all be cured if we only could find an authority to undertake the cure.

Were it not that in many instances we should have men of straw to deal with, we should feel disposed to advocate the application of Lord Campbell's Act to these cases. But as the recovery of damages would be a remote contingency, why should not Local Boards of Health, with their highly-paid health officers and surveyors, be required to see not only that all the details of water supply and drainage in new houses are safe, but that unsafe houses are made safe by their proprietors, or condemned as unfit for habitation?

After all is done, however, the chief remedy must be sought in technical training on all house questions in the application of which scientific principles are involved.

It may be safely stated that there is no technical subject of greater importance than this, and our recent experience has shown that there is no subject on which more training is necessary than to build a comfortable healthy dwelling.

SUTTON'S VOLUMETRIC ANALYSIS

Volumetric Analysis. By F. Sutton. Second Edition. (London: J. and A. Churchill.)

THE present volume is almost the only representative of a considerable branch of chemistry. We are surprised that Volumetric Analysis has not come into more

general use amongst chemists, for the saving of time in most instances is very great, whilst for accuracy it frequently surpasses gravimetric analysis. Since the last edition of this work was published (1863), chemistry has made great advances; in volumetric analysis there has been a gradual extension and development, although nothing very new or startling has taken place during this period. This edition is a far more handsome volume than the last, the type and engravings being everything that can be desired. The author states in his preface that the new system of atomic weights has been adopted; the nomenclature also has been changed to a great extent, although we are sorry to find that the system adopted is by no means perfect. Thus we read of "the carbonates of lime, baryta, and strontian" (p. 26), whilst in a later part of the book such terms as "hydric chloride," &c., are met with. These of course are extreme cases; would it not have been better to have adopted some definite system throughout the book? We regret to say that the larger portion of the book is disfigured by a great number of small errors; for instance, the cross references in many cases are wrong, thus at page 80, the reader is referred to § 80, 2, for the determination of chlorides by Liebig's method, the paragraph referred to is an article "on the examination of raw phosphates and phosphatic manures." Again, we are told on p. 116 to refer to § 71 for the titration of phosphate, but this paragraph describes the estimation of sulphuretted hydrogen. We have noticed so many errors, some in formulae, some in equations, and again in grammar, that, though making every allowance for printer's errors, we must conclude that the edition has been carelessly revised. There is one paragraph we should wish to call attention to, the first on p. 132, which we confess we have not been able to understand clearly. The number of new processes introduced is not large, nor are they of very great importance. We think, however, that methods such as the estimation of nitric acid by indigo might have been omitted, and that, for instance, the iron process for phosphoric acid might have been introduced. If Mr. Sutton would give, as far as possible, the precise cases for which each process is most suitable, we think the value of the book would be much increased. His long experience in these matters would render this addition of great importance, and would save much trouble.

Fifty-four pages of the volume are occupied by a description of the processes of water analysis (furnished by Mr. W. Thorp); this consists of a lengthy description of Frankland and Armstrong's process, which has undergone considerable modification, and a much shorter description of Wanklyn and Chapman's process. We look upon this part of the book as very valuable, for water analysis has now become quite a study, and such a clear and concise statement as that in the present volume will be found of great service to any one engaged in this work.

The last section of the book, consisting of seventy-four pages, is "On the Volumetric Analysis of Gases," contributed by Prof. H. McLeod. We cannot praise this portion of the volume too highly, the engravings are excellent, many of them we believe being from the original drawings of the author. We do not think that any student could do better than take this as his guide to gas analysis. It is the most clearly written and practical

account that we have seen in the English language, and we should be glad to see it still further extended by the author.

On the whole Sutton's "Volumetric Analysis" has certainly improved on the first edition, but with more care its value would have been much increased.

MORELET'S TRAVELS IN CENTRAL AMERICA

Travels in Central America, including Accounts of some Regions unexplored since the Conquest; from the French of the Chevalier Arthur Morelet. By Mrs. M. F. Squier. Introduction and Notes by E. G. Squier. (London: Trübner and Co., 1871.)

IN that portion of Central America which lies between Yucatan on the north and the city of Guatemala to the south, and bounded on the east by British Honduras, is a considerable tract of country which has remained almost unknown to Europeans since the Spanish conquest, and in which the traditions of the neighbouring States place vast aboriginal cities and wonderful enchanted lakes. To explore this region was the object of the adventurous expedition of M. Arthur Morelet, a French gentleman of leisure and extensive scientific acquirements. M. Morelet's natural history collections were deposited in the Museum of Paris, and described in the *Comptes Rendus* of the Institute; a new crocodile was named after him (which he pathetically declares to be the only result of the journey as far as fame to himself is concerned), and an account of his travels was printed for private circulation in his own country. In the volume before us a portion of this is now translated for the benefit of the American and English public. Although the work records no important or striking discoveries, it is a valuable and interesting contribution to the geography and natural history of an almost unknown district.

M. Morelet's journey was divided into two portions. The first was devoted to a visit to the ruins of the ancient city of Palenque, near the great river Usumasinta, in the western portion of the district. The existence of these ruins was not known till 1750, but they have been sufficiently described in the works of Dupaix, Stephens, and others. Notwithstanding the traditions of immemorial antiquity which hang around them, the author attributes their origin to the Toltecs, who, in the middle of the 7th century were in possession of Anahuac, where civilisation peaceably developed itself. Later, about the year 1052, they abandoned this region, and emigrated in a south-easterly direction, that is to say, into the provinces of Oaxaca and Chiapa. It is easy enough, therefore, he thinks, to arrive at the conclusion that Palenque was founded at this time, and was consequently contemporaneous with Mitla.

The second and more important portion of M. Morelet's expedition had for its special object a visit to the great lake of Itza, situated in the province of Peten. Although nominally within the territory of the Republic of Guatemala, and but a comparatively short distance from the British settlement of Belize, he was unable to obtain at any of the seaport towns of Yucatan any exact information as to the exact locality of, or the means of access to, this

mysterious region. Proceeding from Palenque up the Usumasinta River, his route then lay eastwards for upwards of a fortnight through virgin forests of great magnificence, abounding in insects of all kinds, and in many rare and curious birds, and with a floral vegetation of great interest and beauty. The author describes in particular the *Aristolochia grandiflora*, with a flower often not less than twelve to fifteen inches in diameter, the calyx resembling the figure of a swan suspended by its bill, but when full-blown assuming the form of the conventional cap of liberty, turned up with a violet velvet lining, and worn by the Indian children as a helmet.

The great lake variously referred to by chroniclers as that of Itza, of the Lacandones, and of Peten, is described by M. Morelet as having a circumference of upwards of twenty-six leagues, and a depth in most cases exceeding thirty fathoms. It is not fed by any river, or even brook, of importance, and has no outlet; how its waters are kept fresh is not described. Its shores are defined by a girdle of broken calcareous hills, which are more or less silicious. On an island situated near its south-western shore is the Indian town of Flores, the only one of importance in this vast, almost uninhabited, district. Its description, and the illustration, convey an idea of great beauty:—

"I was impressed with the magnificence of the landscape which presented itself from the eminence where the modern church is situated, and which was once occupied by the ancient temples of the Itzaes. The sky was clear, the waters of the lake of the loveliest azure, and the islands and bluff shores, indented with little bays, hemmed in by silvery belts of sand, were green and refreshing to the sight. The island of Peten itself is oval in shape, rising by a gentle slope from the water, and terminating in a platform of calcareous rocks. It is not large; one may make the circuit of it in a quarter of an hour. Its surface is covered with small stones, which are doubtless the remains of ancient edifices."

The necessities of life, both as to food and clothing, being very few in number, the inhabitants of Flores have little inducement to labour, and pass their days in luxurious idleness or nocturnal festivities, and their character is what might be expected from their habits of voluptuous ease, though without any strongly developed vices. As to the natural history of the district, the author describes as the most abundant mammalia three species of deer, the tapir, the peccary, a species of rabbit, an armadillo, the agouti, which commits great ravages on the crops, and several rodents. Among the birds he mentions particularly a small heron (*Ardea exilis*), two swallows, and a humming bird. Among the reptiles are a number of species hitherto undescribed, including a new turtle (*Emys arvolata*) and the *Crocodilus Moreleti*, the capture of which nearly cost him his life. There are fifteen different kinds of fish in the Lake of Itza, which are almost without exception peculiar to it. Considering the isolation of the lake from all other water systems, this fact is of great interest to the student of the geographical distribution of animals, and of the origin of species. The flora is not described in detail, indeed throughout the book few plants are specifically named, unless of striking beauty or producing edible fruits. A suspicion of the accuracy of the author's knowledge of natural history is excited by the occurrence of such phrases, unless they be due to incorrect translation, as "invertebre (*sic*) and

insects," speaking of a gastropod as a "shell-fish," and describing the *Tillandsia* as "a variety of moss." Another serious defect in the book is that the map which accompanies it does not correspond with the text in the spelling of the names, nor always even in the natural features of the country.

From Flores M. Morelet proceeded in a southerly direction to the City of Guatemala, passing along the watershed which separates the streams flowing into Honduras Bay on the east from those which find their outlet in the Gulf of Mexico to the west. A halting-place on the route is the station of Campamac, laid down on the maps as a place of some importance, but which he found to consist of "half-a-dozen worm-eaten posts stuck in the ground in the midst of the forest, and supporting a thatched roof; a small clearing in front, and faint traces of a path leading to it in one direction, and from it in another." A little farther south, on approaching the Indian town of Cahabon or Cajabon, the traveller emerges from the dense virgin forests which have clothed the country since he left Flores, and enters on the wide open savannahs which characterise the southern portion of Guatemala. The Indians of this district belong to a different race from the Mayas of Peten; they are of a darker colour, with less regular features and less symmetry of form; with low foreheads, high cheek bones, and the top of the head rising to a point in a manner apparently artificial. The civilisation introduced by the Dominicans appears to be gradually decaying; and European vices, added to their own national indolence, are rapidly reducing their numbers, and deteriorating their character.

The reader will find in M. Morelet's narrative much valuable information as to the manners and customs of the inhabitants of an almost unknown territory, and with regard to the physical features and natural history of a country extremely rich in natural productions; interspersed with those personal incidents and tales of romantic adventure which add so much to the charm of a book of travel.

OUR BOOK SHELF

The Ornithology of Shakespeare. Critically examined, explained, and illustrated. By James Edmund Harting, F.L.S., &c. (London: Van Voorst, 1871.)

THE man who wrote the line, "One touch of Nature makes the whole world kin," demands that some notice should be taken in these columns of any one of his numerous commentators who may attempt to set forth that side of our versatile poet which turns towards natural history. Mr. Harting's attempt is eminently successful. We last met with him (not long since) "on the lone sea-shore," we now find he is equally at home in the library, and if he does not convince us that Shakespeare was a greater ornithologist than has lived since, proof at least is adduced that he was, in his knowledge of birds and their ways, inferior to no one of his time. Books have been written to show that our immortal bard was a soldier, a lawyer, and what not—his reputation as a keen and accurate observer of the feathered race is now fully established. How, indeed, could it be doubted? Did not the "swan of Avon" appreciate "the temple-haunting martlet" and the delicate air which it loved? Did he not "tune his merry note unto the wild bird's throat" while celebrating equally "the clamorous owl that nightly hoots," and "the plain-sung

cuckoo grey?" But here we must stop. It is always the reviewer's business ("tis true, 'tis pity, and pity 'tis, 'tis true") to point out defects. We may mention one. Mr. Harting has forgotten to notice the correct interpretation of the expression "russet-pated choughs," and urges the claim of the jackdaw to be the bird so distinguished. Now, as he truly says, the daw has a grey head, and to make Shakespeare term grey "russet" is, in our eyes, a crime. Without doubt the poet had in his mind the real Cornish chough, and the expression is quite accurate. "Russet-pated" is having red *pattes* or feet (*cf.* the heraldic *croix patée*); not a red *pate* or head—a feature equally inapplicable to chough or daw, while the red feet of the former are as diagnostic as can be. We are bound to say, however, that such a slip as this stands alone. Mr. Harting's book in general is not only readable, but exact and instructive, while its illustrative woodcuts are well chosen, well drawn, and well engraved.

Thoughts on Life-Science. By Edward Thring, M.A. (Benjamin Place), Head-Master of Uppingham School. Second edition; enlarged and revised. (London and New York: Macmillan and Co.)

THE first edition of this book by the accomplished and efficient head-master of Uppingham School appeared with the pseudonym "Benjamin Place" on its title-page; this second and much-enlarged edition bears the author's own name. The title may be apt to mislead some as to the nature of the contents; it is not a work on Biology. The author apparently means by "Life-Science" the science of those phenomena which are the manifestations of the higher kinds of life, as opposed to those sciences which deal with "matter animate and inanimate." "The world open to man's intelligence," he divides into two parts: "On the one side there is matter animate and inanimate, which as matter is capable of material investigation, and which is below man. On the other side there is life as displayed in feeling and thought, and belief founded on the facts of life. The science of this is Life-Science." Mr. Thring believes that man cannot live by science alone; that there is a kind of knowledge, a circle of belief, a region of activity, quite outside and independent of science strictly so-called, and which is of far more importance to the great bulk of humanity than any amount of scientific knowledge. To Mr. Thring, in the present "displacement of traditional ideas, it has seemed no useless task to look steadily at what has happened, to take stock, as it were, of man's gains, and to endeavour, amidst new circumstances, to arrive at some rational estimate of the bearing of things, to examine the instruments and means at our disposal, to examine our strength; so that the limits of what is possible, at all events, may be clearly marked out for ordinary persons." "This book is an endeavour to bring out some of the main facts of the world." Mr. Thring puts forward many statements regarding the inadequacy of language as a vehicle for thought, and on the imperfection of human intelligence itself at the present stage of man's progress, which claim the consideration of all those who are inclined to deny them; and much of what he says, as to the sphere and power of scientific research, deserves to be pondered by all earnest seekers after truth, and, indeed, has almost always been admitted by the highest intellects, who have tried to explore "the great ocean of undiscovered truth." Mr. Thring's style is characterised by a rugged force, and a certain novelty of expression and even of construction, which will render his book interesting to many readers, and which are frequently the outcome of his intense earnestness and the thoroughness of his convictions, as well as of impatience with those intolerant scientific specialists who imagine the little group of phenomena that comes within the ken of their limited vision to be the universe. We heartily commend the book to the attention of our readers.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Dr. Carpenter and Dr. Mayer

WITH reference to Dr. Tyndall's communication of last week, in which I most unexpectedly found a private note of my own placed before your readers, I should be obliged by your allowing me to state:—

1. That the idea of "Correlation," as originally entertained by Mr. Grove, and applied by myself to physiology more than twenty years ago, most unquestionably included that of the *quantitative equivalence* of the convertible forces, as will appear from the following passage in my memoir of 1850 (Phil. Trans. p. 731):—"The idea of correlation also involves that of a certain *definite ratio* between the two forces thus mutually interchangeable, so that the measure of force B, which is excited by a certain exertion of force A, shall, in its turn, give rise to the same measure of force A as that originally in operation." And further I urged the *precise relation* observable between the vital activity of plants and cold-blooded animals, and the amount of heat they receive from external sources, as a ground for the belief that heat has the same relation to the organising force as it has to electricity (pp. 747-750).

2. In crediting Dr. Mayer therefore with the independent (and in my own case the previous) enunciation of the "Correlation" doctrine, I most certainly meant to include the notion of *quantitative equivalence*. Whether the quantities be or be not expressed in number seems to me a matter of secondary importance.

WILLIAM B. CARPENTER

University of London, Dec. 26

The "North British Review" and the Origin of Species

THE writer of the article on the "Origin of Species," which was published in the *North British Review* for June 1867, has corrected in your periodical for November 30 an important error which occurs in a certain paragraph of that article. There is, however, it appears to me, a much more serious error in the same paragraph, which vitiates his arithmetical calculations throughout, and leads him to an erroneous conclusion.

The paragraph in which this error occurs is quoted at length in Mr. Mivart's work on "The Genesis of Species." It may therefore be worth while to point out the oversight alluded to.

The error arises from the writer's assuming that in a race which remains constant in numbers, only one individual out of each family, *i.e.*, out of the offspring of one female, will on an average survive to produce young. This assumption is not true; for since only one half of the race, namely the females, bring forth young, it follows that two out of each family must, on the average, survive to have offspring, namely, one male and one female. Each of these will transmit its peculiarities to its descendants.

I will now quote the writer's words, putting within brackets the necessary corrections.

He says, "A million creatures are born; 10,000 survive to produce offspring. One of the million has twice as good a chance as any other of surviving; but the chances are 50 to 1 against the gifted individual being one of the 10,000 survivors." Further on he says, "Let us consider what will be its influence on the main stock if preserved. It will breed and have a progeny of, say 100; now this progeny will, on the whole, be intermediate between the average individual and the sport. The odds in favour of one of this generation of the new breed will be, say, $1\frac{1}{2}$ to 1, as compared with the average individual; the odds in their favour will therefore be less than that of the parent, but owing to their greater number the chances are that about $\frac{1}{2}$ of them would survive [about 3 of them, for without any advantage two would on an average survive.] Unless these breed together, a most improbable event, their progeny would again approach the average individual; there would be 150 [300] of them, and their superiority would be, say in the ratio of $1\frac{1}{2}$ to 1; the probability would now be that nearly two [$6 \times \frac{1}{2}$, or nearly 3] of them would survive, and have 200 [750] children with an eighth superiority. Rather more than 2 [15] of these would survive; but the superiority would again dwindle, until after a few generations it would no longer be observed, and would count for no more in

the struggle for life than any of the hundred trifling advantages which occur in the ordinary organs."

The writer thus concludes that the advantage derived by inheritance from the sport will ultimately die out. The true conclusion is, that the advantage never dies out, but only becomes distributed through the whole race; and, moreover, that the sum of the advantages of all the favoured individuals, when added together, is greater than the original advantage, and becomes greater and greater every successive generation, though it tends to a limit at which it never actually arrives. Thus, representing the original advantage by unity, the advantage in the next generation is $1\frac{1}{2}$, in the next $1\frac{1}{4}$, and so on.

If now the same kind of sport arise independently, (*i.e.* not by inheritance from some previous sport) say once in every generation, and is preserved, say once in every fifty generations, the advantages derived by inheritance from these sports will accumulate and become distributed throughout the whole race. Hence in the course of an immense number of generations they must produce a decided effect upon the character of the race.

Thus, though any favourable sport occurring once, and never again, except by inheritance, will effect scarcely any change in a race, yet that sport, arising independently in different generations, though never more than once in any one generation, may effect a very considerable change. These conclusions are opposed to those which the writer of the article is endeavouring to establish.

Leeds Grammar School

A. S. DAVIS

Prof. Tait on Geological Time

AS I have lately found, under the signature of Prof. Tait, in the well-known *Revue Scientifique*, several statements that would doubtless have been challenged had they appeared in any English scientific journal, and of which the following are specimens:—"Sir W. Thomson has already demonstrated, by three complete and independent physical proofs, the impossibility of admitting the existence of such periods"—"Each one (of Sir W. Thomson's arguments) would suffice to upset at once the pretensions of Lyell and Darwin"—"Professor Huxley's attempt has completely failed;" and as in the new edition of Jukes's *Geology* Sir W. Thomson's demonstration is stated at some length, while an adverse argument used by Jukes is omitted, I venture to ask that you will allow me a few words on the subject, since I treated the matter at length two years ago in *Scientific Opinion*, and, so far as I am aware, my arguments remained unanswered.

1. Does not the conclusiveness of all Sir W. Thomson's arguments depend upon the assumption of the universality of the principle of dissipation of energy? But to assume this is to assume that uniformitarianism is false. The whole question is therefore begged in the premisses, as must be the case in mathematical arguments.

2. As Mayer categorically denies the universality of the said principle, by what right does Sir W. Thomson entitle it a "principle of natural philosophy," and therefore state that uniformitarians are "directly opposed to the principles of natural philosophy"? As in the opinion of the French Academy, and of many eminent English and German savants, Mayer is one of the first physicists in Europe, I think it cannot be assumed with Prof. Tait that, "as regards method, Mayer and his supporters are little in advance of the Middle Ages," though undoubtedly Mayer is very different from Sir W. Thomson.

3. By what process does Sir W. Thomson discover "universal principles"? His universal principle regarding the origin of life "true through all space and all time," affords an opportune answer to this question. I would simply refer to Mr. Ray Lankester's article on that principle (*NATURE*, No. 97, p. 368), and ask if any one can discover a more satisfactory foundation for the *universal* principle of dissipation. From long study of Sir W. Thomson's reasonings, I conclude that he will reject any evidence for spontaneous generation, in consequence of the "universal principle" he has assumed on that question.

4. In Section A of the last British Association, Sir W. Thomson supported his argument regarding the form of the earth (controversied in your pages by Mr. Croll) by referring to existing mountains five miles high (see *Athenaeum* report). His audience must have understood that these mountains are primeval, as otherwise the argument would have had no meaning. But as this is the reverse of the truth, I cannot help saying that Sir W. Thomson appears to consider himself entitled, not merely to invent principles, but also to invent facts. I know no conclusions of

science that might not be "briefly refuted" by such a method; but I think it would be fair to employ the words, "particular opinions of Sir W. Thomson" in place of "principles of natural philosophy," and "imaginary consequences of these opinions" in place of "facts." If this were done, all would admit that Sir W. Thomson's arguments are conclusive demonstrations; granted the premises, the conclusions certainly follow. But geologists have simply to assume the contrary premises, and they may mathematically demonstrate the reverse. Agree to beg all the difficulties of a question, and a certain conclusion may easily be obtained. This fact was recognised in the Middle Ages, and Mayer has not got rid of it.

P. W. STUART MENTEATH

12, Rankeillor Street, Edinburgh

[The remarks of Prof. Tait are contained in his opening lecture for Session 1869-70, which was sent to us with permission to make what use of it we chose. As the matter of Geological Time had been very fully discussed in this country, we did not insert the portions bearing on it. We believe that the portion which we did insert induced the editor of the *Review* to apply to the author for the whole MS. As to the queries in the above letter we may note,

1. The Dissipation of Energy is a necessary consequence of the second law of Thermodynamics.

2. If "Mayer categorically denies its universality," so much the worse for his own credit, and for that of "the French Academy and the eminent English and German savants" who support him.

3. It is not for us to say what Sir W. Thomson would, or could not, do.

4. So, after all, Mayer seems to be no better than Sir W. Thomson.—ED.]

In Re Fungi

It may allay the alarm of your correspondent "W. G. S." as to the decay of fungology in England, as far, at least, as one of the cases which he quotes is concerned, to be informed that so careful and critical a student of fungus as Mr. W. G. Smith confirmed the determination referred to, and on the faith of the abnormal specimen, included this rare and very critical species without any hesitation among the Middlesex fungi in the "Middlesex Flora," p. 408. Your correspondent "W. G. S." has missed the point of the paragraph from the *Journal of Botany* which he criticises. The specimens of this fungus collected by Mr. Wooster at Whitehall Gardens have a regular and normally developed pilus, and were in striking contrast to the "abnormal specimens" (W. G. Smith, *l. c.*) from the Goswell Road.

A Shadow on the Sky

I do not know how common is the phenomenon described by Mrs. Charlotte Hall in *NATURE* of Nov. 9 (p. 25), but her communication leads me to report a much less striking appearance of the same kind, which I witnessed Feb. 20, 1870, in this neighbourhood. I was taking an early walk, and had mounted to the top of a ridge commanding an eastern view, about fifteen minutes after sunrise. The sky was veiled in a dark white. Above me, a little to the south and east, hung a ball of vapour in mid-air, warmed into smoke-colour by the rays of the sun, and yet so dense as to cut off these rays, and cast a rectilinear shadow of dark blue against the white coat of the sky. The shadow was sharply defined, and the whole effect was not unlike the nucleus and tail of a comet. In a few moments the shadow faded out, and, shortly after, the ball itself was dispersed. The moon, in its third quarter, was visible somewhat past the zenith, and surrounded with vapour. Twelve hours later we had a violent rainstorm.

New York

Coal Measures of Ireland

In the new edition of Jukes's "Manual of Geology," by Prof. Geikie, at page 592, it is stated, on the authority of Mr. E. Hull, that "in Leitrim, Fermanagh, and Tyrone, there are true representatives of the Yoredale series of England." I, however (as also the late Mr. Jukes), contend that no comparison can be drawn between the coal-bearing rocks of Ireland and those of England. Furthermore, as Mr. Hull is unacquainted with these

Irish rocks, having only seen a few isolated patches of them, I protest against his being quoted as an authority on the question, more especially as in the paper to which Mr. Geikie referred, "On the Geology of the Ballycastle Coal Fields, &c.," Mr. Hull states that while in the counties above mentioned there are true coal measures, in the provinces of Leinster and Munster there are none—a statement quite contrary to facts, as all the sections of these rocks in Leinster, Munster, and Connaught are identical, and probably, as suggested by the late Mr. Jukes, were once connected, as the lowest bed of coal occurs everywhere at a nearly equal height above the limestone. Furthermore, the intervening strata are nearly identical, there being a certain thickness of argillaceous beds below, next the limestone, and a mixture of arenaceous and argillaceous beds above.

Naturally it may be expected in all places where a sea gradually became shallow, that limestone would be succeeded by fine argillaceous beds, the latter by shore beds, more or less coarse and arenaceous, and eventually by land beds, such as coal, fire-clay, clunch, and the like.

Similar sequences are not uncommon, both on a large and small scale. On the large scale in the passage rocks from the limestone to the coal-bearing rocks of most countries, and on a small scale in the north of Ireland and in Scotland, where a bed of limestone will be succeeded by a shale, the shale by a sandstone, and the latter by a clay or coal.

If we examine into the thickness of the English and Irish rocks, the difficulty of a comparison is apparent. In the latter country the greatest thickness of the rocks called coal measures never exceeds 3,500 feet, this series of strata including all the rocks above the limestone; whilst in Lancashire, according to Mr. Hull's sections, the Yoredale beds alone exceed 5,000 feet in thickness.

Moreover, if any value is to be attached to paleontological evidence, we find that from the base upwards in the Irish rocks there are fossils which in England are considered to be characteristic of the true coal measures. The latter fact would seem to suggest that while in Ireland the upper part of the limestone was being deposited, in England the millstone grits and Yoredale rocks were accumulating, whilst subsequently, in both countries, true coal measures were deposited; those in Ireland being unfortunately very poor in coal, although containing very similar fossils.

In the northern extremity of Ireland, and in Scotland, the measures are very similar, and in certain places apparently identical, as pointed out years since by Sir R. Griffith. This, therefore, is no new fact, as Messrs. Hull and Geikie would suggest to their readers.

G. HENRY KINAHAN

Recent Changes in Circumpolar Lands

SOME years ago I wrote a paper for the Ethnological Society on some changes of surface affecting Ancient Ethnography. Since this was printed many facts have accumulated. These have led me to a tentative generalisation on the subject, which I should like to have discussed in your pages.

The question of the upheaval and subsidence of different areas of the earth's surface, as it is going on at the present moment, is of very great importance in geology, and yet few subjects have been more neglected. A few facts have been here and there collected; but even the best authorities treat the matter in a jejune fashion. According to them the areas of upheaval and subsidence are scattered over the earth's surface in an irregular manner, without any definite law or rule. I believe that with very slight local exceptions there is a very distinct law which governs the subject.

Putting aside altogether the southern hemisphere for the present, I wish to prove that the area of upheaval is confined to the land bordering the Polar Sea, and to the Polar Sea itself; that it is perfectly continuous all round the earth, and that it is greatest near the Pole, and gradually diminishes until it disappears about the 57th parallel, leading to the conclusion that the focus of upheaval is the Pole itself.

Of course, my observations are entirely confined to what is taking place *now*, and are not to be confused with the facts of any other period, historical or geological.

Commencing with Scandinavia, we have the remarkable testimony of Pliney, Mela, Solinus, and others, to the fact that Scandinavia was considered by the Roman geographers, whose authorities were bold and expert seamen, to be an archipelago. Ptolemy speaks of the Scandian Islands. The very name Scandinavia is evidence that those who used it looked upon it as an

island. This implies that a great deal of dry land must then have been under water. In 1834 Sir Charles Lyell wrote his Bækerian lecture, in which he brought forward overwhelming evidence to prove that Scandinavia was then being gradually upheaved. Cælius, who wrote in the 17th century, had affirmed it, and calculated the rise at forty inches in a century. In 1807 Von Buch wrote that all the country from Frederikstadt, in Sweden, to Abo, in Finland, and perhaps as far as St. Petersburg, was slowly rising. Other authorities concurred, and lastly Sir Charles Lyell, who had approached the subject as a sceptic, was fully convinced after an exploration of the ground. At Stockholm he found striking proofs of change since the Baltic acquired its present tenants. Testacea found there seventy feet above the sea level being identical with those found in the adjacent sea. At Soderleige, a little farther south, and in a bed ninety feet above the sea level, besides the shells were found several buried vessels, made of wood, and joined with wooden pegs. In another place an iron anchor and nails were found. At Upsala brackish water plants were found in meadows where there are no salt springs; a proof that the sea had only recently retired. At Oregund, forty miles to the north, the land had risen five inches and a half since 1820, and at Gefle were low pastures, where the inhabitants' fathers remembered boats and even ships floating. Experienced pilots in the Gulf of Bothnia estimated the fall of the waters at two feet in thirty years. Since Sir Charles Lyell's lecture both the Russians and the Swedes have made experiments all proving the same fact.

To the east of Scandinavia we have Finland, exhibiting all the characteristics of a recently-emerged land. It is a mere congeries of lakes and swamps, separated by moss and sand. The level of the lakes is constantly falling. In 1818 Lake Sovando was suddenly lowered; its waters escaped into Lake Ladoga, and much of its bottom was exposed. Similar traditions about low meadows but recently crossed by boats and ships to those existing in Sweden prevail here also, and there seems good ground for believing that in the days of the Norsemen the White Sea and the Gulf of Finland were joined by a considerable strait. Farther east, again, we have the experience of Murchison and his companions, who found on the banks of the Dwina and Vaga recent shells still retaining their colour, and of the same species as those found in the Arctic Sea. In Spitzbergen, Mr. Lamont reports (see vol. xviii. of the "Quarterly Journal of the Geographical Society") that he discovered recent bones and drift wood several miles inland and high above high-water mark, skeletons of whales thirty to forty feet above the sea level. The seal fishers told him the land was rising, and that the seas thereabouts were now too shallow for the right whale, which had forsaken the Spitzbergen coast. This is confirmed by Malmgren (see Petermann's *Mittheilungen*, 2, 1863). Farther east we have the Tundras between the Karen Sea and the Gulf of the Obi presenting bare desolate flats that look as if they had only recently emerged. Middendorf describes the surface of the great Siberian Tundra as coated with fine sand like that now being deposited by the Polar Sea. Von Wrangel has many useful remarks to prove my position. He tells us that Diomed Island, mentioned by Laptev and Schalaurow, is now joined to the mainland; the coast of the Swatow Ness, which they describe as very indented and ruinous, is now straight. The Bear Islands are mere heaps of ice and stones, evidently but recently covered with water; and shoals and banks now occupy what was tolerably deep water in 1787 when Captain Sarypchev was there.

Herdstrom, in 1810, found large birches scattered about the Tundra, 3° to the north of any known Siberian forest; probably drift wood such as Wrangel himself found drifting in the Polar Sea. Whales have now almost deserted the Siberian shores, where in the eighteenth century they were common. This is, no doubt, due to the shallowing of the water, as is the case in the Spitzbergen Sea. The shores of the Polar Sea, from the Lena to Behring's Straits, are for the most part low and flat. In winter it is hard to say where land ends and sea begins. A few versts inland, however, a line of high ground runs parallel with the present coast, and formerly, no doubt, constituted the boundary of the ocean. This belief is strengthened by the quantity of drift wood found in the Upper Level, and also by the shoals that run out, and will, no doubt, become dry land (*Vide* Wrangel's Introduction). "At several places along the coast we found old weathered drift wood at the height of two fathoms above the present level of the sea, whilst the lower drift wood lay at a level, indicating a change of level." Moving farther east again across Behring's Straits, we find Captain Beechey describing the coast as a high cliff, now separated from the sea by low flats with

bones, &c., on them. I cannot speak with the same confidence of the vast archipelago that bounds America on the north, nor about the northern shores of America, my researches having been confined to Asia, but evidence must abound in the Arctic voyages. Drift wood and bones of whales are mentioned on high ground by several of them. If it be permitted to quote the works of M. Reclus as an authority, and I believe it to be a most sound book, he says, page 628, numerous indications of the phenomenon (*i.e.* of the upheaval of the circumpolar land of North America) have been recognised in the Arctic islands, scattered off the coasts of the Continent. At Port Kennedy Mr. Walker found shells of the present period at a height of 557 feet above the sea; a bone of a whale lay at a height of 164 feet. Again, page 651, after saying that Southern Greenland is being depressed, he continues, "On the north of Greenland, from lat. 76°, and in Grennell's land, &c., the directly contrary phenomenon is taking place." Hayes discovered on all the coasts the existence of ancient sea-beaches which had gradually risen to the height of 100 feet.

I have thus shown good ground for entertaining the notion that the land at present rising about the Pole is a continuous area, and is not rising merely in detached masses as M. Reclus and Mr. Murray's maps (Geographical Distribution of Mammals) would lead us to suppose. I believe, further, that this area, bounded on the south by about the 57th parallel of latitude, *is the only area in the Northern Hemisphere which is at present undergoing upheaval*. I should feel grateful to any of your correspondents who would point out where there is another area (of course excepting local disturbance immediately round a volcano); or would direct me to any authorities throwing light on the question I have advanced, which for anything I know may be an old theory, or even an exploded heresy.

Not only is the land around the Pole rising, but there is evidence to show that the nearer we get to the Pole the more rapid the rise is. This has been shown most clearly in the case of Scandinavia by Sir Charles Lyell, who most carefully gauged the rise at different latitudes from Scania, where the land is almost stationary, to the northern parts of Norway, where the rise is four feet in a century. While in Spitzbergen and the Polar Sea of Siberia, if in the memory of seal fishers and others the water has shallowed so fast as to have excluded the right whale, we may presume that the rate of emergence continues to increase, until it reaches its focus at the Pole, as it certainly diminishes until it disappears towards the south between the 56th and 58th parallels of latitude. The subject is one of paramount importance to those who are trying to work out the history of the earth, and I once suggested at the British Association that it should be made the work of a special report, but I was snubbed. I appeal with more confidence to you, sir, to help me to ventilate it. The question of the subsidence of other areas, and of the correlated climatic change, I will reserve for another letter.

HENRY H. HOWORTH

Derby House, Eccles

THE ENGLISH GOVERNMENT ECLIPSE EXPEDITION

MANY of the readers of NATURE are no doubt interested in the fate of the Eclipse Expedition of 1871. I will therefore give a sketch of their doings to the present time.

The P. and O. steamer *Mizapore*, having the party on board, left Southampton on Oct. 26, and, after a rather rough voyage, reached Malta on Nov. 4; left again the same evening, and arrived at Port Said on the 8th; entered the Canal at once, and anchored at Suez on the 10th. Here she remained till the 12th, awaiting the arrival of the Brindisi mails; then left for Galle, where she arrived the 27th. On leaving the Channel a strong S.W. breeze was encountered, which soon increased to half a gale. The ship, though a roller, is a good sea boat, and made good progress; but the bad weather continued with little abatement until the *Mizapore* was well in the Mediterranean, and nearing Malta. The sea then became calmer, the sun shone out, and the passengers, many of

whom had not before emerged from their cabins, now came out as gay as possible, ready to make an impression at Malta. Our astronomers, who had not been exempt from the common fate of those who try the sea without a special education, now quickly roused themselves to make use of the opportunities for overhauling their instruments, and practising themselves for the work before them. The officers of the ship kindly gave every assistance, and those instruments that could be used on so unsteady a platform as a ship's deck were brought up from the hold, in which they had lain safely during the gale in the Bay, mounted on temporary stands, and used most diligently to investigate the changing phenomena with which we were surrounded. Classes also for mutual instruction were formed, so that each observer, on being detached in India, might—no matter what his special forte, whether spectroscope or polariscope—be able to impart instruction to the volunteers that we hope to obtain in India to aid in the good work. Our party numbered ten, viz.: Mr. Lockyer, chief, Messrs. Abbay, Moseley, Friswell, Capt. Tupman, R.M.A., and Commander Maclear, R.N., spectroscope observers; Dr. Thomson and Mr. Lewis, polarisers; Mr. Holliday, artist; and Mr. Davis, photographer. At Suez we were strengthened by the addition of Signor Respighi, from Rome, who has so distinguished himself by his observations of the solar atmosphere. The other passengers took great interest in the doings of the "Wise Men of the East," as they called us, and at their request, the day before arrival at Malta Mr. Lockyer gave a lecture on the advances that had been made of late years in solar physics, and on the object of this expedition.

Observations were made, as opportunities were given by clear sunrise and sunset at sea, on the alterations that take place in the absorption bands as the sun rises from the horizon; and here may be mentioned the interesting result, that whilst in the open sea the bands at sunrise and sunset were, with slight variations, the same as observed by Lieut. Hennessey (paper read before the Royal Society May 21, 1870) whilst passing through the Suez Canal and down the Red Sea, the lines attributed to aqueous vapour near C and D were weaker, and although the colour of the hills about Suez was of a delicate purple, especially at sunset, the violet end of the spectrum could hardly be seen.

In the Indian Ocean, when the air was close and filled with moisture, and the N.E. monsoon blowing, the absorption bands near the horizon became very strong, and it was very interesting during the afternoon to fix a telescope with spectroscope attached, so that the horizon bisected the field; the spectrum of the air above the horizon then gave the absorption bands, but they were very faint in the light reflected on the water from the upper part of the sky, and they could be seen lengthening and shortening as the ship rolled towards or from that side. On pointing the spectroscope at the sky above, only the ordinary solar spectrum could be seen.

The Canal was entered on the 8th of November about 3 P.M., and the ship anchored at Suez at noon on the 10th. The *Mirzapore* is one of the largest vessels that has passed through the Canal, and though she got through safely, it must not be supposed that she did not touch at all; in fact, the Canal is so narrow that too little room is left to allow for the time that so long a ship (400 feet) requires to answer her helm, especially at slow speed; and though the helm was shifted, and in some cases the engines reversed, as soon as the bow deviated from the straight line between the piles marking mid-channel, she could not be prevented touching several times. The narrowness also occasions delay when two vessels have to pass, one having to haul close in to the bank, and make herself as small as possible while the other goes by. But it is a grand work, and we have fully experienced the advantage of it, in avoiding the trans-shipment of our instruments, and the rough handling they would have experienced crossing the

desert. We anchored in the Bitter Lakes on the evening of the 9th. The cause of the name they bear was shown by the fact, attested by our engineer, that the water was much saltier than in the canal on either side.

On arrival at Galle we were delighted to find that Admiral Cockburn had brought his flag-ship the *Glasgow* to meet us, and convey our Indian party to Beypoor and Baikul. He has kindly placed all his accommodation at our disposal whilst he visits Ceylon. All our instruments were embarked yesterday, and we leave this morning for Beypoor, where we hope to arrive on the 2nd. The colonial steamer *Serendib* left yesterday with the parties for Jaffna and Trincomalee.

I can now give you the last dispositions of our party. In consequence of M. Janssen taking his station on the Neilgherries, we shall occupy two stations in Ceylon: Jaffna, where will be Captain Fyers, R.E., Captain Hogg, Captain Tupman, R.M.A., and Mr. Lewis; and Trincomalee, Mr. Moseley and Mr. Ferguson.

In India, Baikul or Ootacamund will be our head quarters, occupied by Messrs. Lockyer, Davis, Maclear, and Dr. Thomson; at Manantawaddy, Messrs. Abbay and Friswell; at Poodacottah, Mr. Holliday and M. Respighi.

I hope I shall be able to tell you of the success of our efforts. J. P. MACLEAR

Galle, Ceylon, Nov. 28

The following provisional arrangements have been made in order to save time after arrival at Galle. Observers are warned that they are liable to alteration on receipt of information from the Indian and Ceylon authorities:—

1. The expedition will be divided into six parties as follows: (1) Lockyer, Thomson, Maclear; (2) Respighi, Holliday; (3) Tupman, Lewis, Ferguson; (4) Abbay, Friswell; (5) Moseley; (6) Davis.

2. Each party will be under the charge of the observer just named in each party, who will be held responsible for the instruments, &c., detailed for the use of observers. He will also be the channel of communication with the local authorities, and will make arrangements for the observations to be made by local volunteers.

3. Special instructions will subsequently be issued for the observations, and stations will be named. Each observer will be responsible to the chief of the expedition alone for these observations.

4. The observers in charge of each party will hand in to the treasurer a receipt for the instruments, &c., detailed for each party.

5. The observer in charge of each party will make a list of the cases containing the instruments, &c., and will arrange for their transfer from the *Mirzapore*, and for their future transit.

6. He will be held responsible for the repacking of the instruments after the eclipse, and for their transmission to Galle or Bombay.

To this we are able to append the following official instructions:—

The Ceylon party to be as follows:—Captains Fyers, Hogg, and Tupman; Messrs. Moseley, Lewis, Ferguson, jun., and Fernandez.

Observing Stations to be as follows:—1. Jaffna and station south; 2. A position as far north of Trincomalee as possible, and a station south.

Instruments to be detailed as follows:—recording Dublin spectroscope, Capt. Fyers; tube Dublin spectroscope, Mr. Ferguson; analysing spectroscope, Mr. Moseley; camera, Capt. Hogg; polariscope, Mr. Lewis.

Mr. Fernandez should observe on the central line. He should instruct two observers to make drawings of the Corona on a plan similar to his own near the southern limit of totality.

The recording spectroscope to be used to determine coronal lines in the red end of the spectrum to, and in-

cluding, F. A high power should be used, and the prism should be adjusted for the minimum deviation of the central ray of this portion.

The tube spectroscope should be used in a similar manner for the other part, including F. Intensities referred to F to be most carefully noted.

Care to be taken that observers are not interrupted for two hours after totality.

Instruments to be returned to Galle, and shipped in P. and O. steamer, consigned to J. Browning, 111, Minories, London, E.C. All observations, photographic plates, drawings, &c., to be sent to Mr. Lockyer within a week of the eclipse. Observers to keep exact duplicates in case of loss.

The following resolutions were passed by the Government of India in the Home Department—under date 27th July and 21st October :—

“Colonel Tennant has already been authorised demiofficially to provide the astronomical instruments and photographic apparatus that he will require for his observations, and the Governor-General in Council understands that he is now in communication with Prof. Airy and Mr. Huggins on the subject. The cost of these appliances has been included in the estimate appended to Colonel Tennant's memorandum.

“In addition to these instruments, Colonel Tennant will require the aid of qualified observers, and it has been ascertained that the Superintendent of the Great Trigonometrical Survey is prepared to place the services of Mr. Hennessey and Captain Herschel, belonging to his department, temporarily at the disposal of Colonel Tennant for this purpose without prejudice to their proper duties. The Governor-General in Council approves of this arrangement, and is pleased to direct that the Survey officers above-named shall suffer no loss of their allowances while so employed, and that they shall have their travelling expenses paid out of the allotment of Rs. 15,000 sanctioned on account of the Eclipse observations. Colonel Tennant will arrange with Major Montgomerie beforehand when the officers in question should join them.

“The Governor-General in Council is further pleased to direct that Colonel Tennant shall receive from the Surveyor General's Department all the aid that he may require as regards photographic assistants, chemicals, &c.

“Lastly, the Governor General in Council is pleased to direct that the report of the result of Colonel Tennant's observations, and his accounts, shall be submitted by him to this department.”

“From the correspondence received with the above despatch, the Governor General in Council has learnt that an expedition is being sent out from England under instructions from the Eclipse Committee of the British Association, and he is desirous that the Government of Madras will afford the expedition such assistance as it may require in the furtherance of its operations. Such assistance will probably consist in the provision, on a moderate scale, for three or four persons, at each place selected, of tents, means of subsistence, and locomotion, and in the erection of temporary observatories of a simple form. It may also be desirable to depute one or two persons to each party from the Public Works Department to assist the observers.

“Information has also been received that the French Government has deputed M. Janssen to visit India with the same object, and the Governor General in Council desires that the Government of Madras will afford every facility and assistance to that gentleman also.

“The Financial Department will be moved to sanction any reasonable expenditure that may be necessary to enable the Government of Madras to give effect to these instructions.”

ARCTIC EXPLORATIONS

A SHORT paper of mine on the above subject appeared in *NATURE* of the 7th December, in which I stated some reasons for my belief that Smith Sound possesses no apparent advantages over Spitzbergen as a route by which to reach a very high northern latitude or the Pole itself. In fact I think the advantages are all the other way; and I shall endeavour to show one or two more reasons than I have already given for this belief.

Kane's and Hayes's ships were stopped by ice in Smith Sound before they reached lat. 79°, and this, I think, can readily be accounted for by the peculiar contour of the coast-line, as may be seen by the accompanying rough outline, taken from a copy of Dr. Hayes's chart in the Royal Geographical Society's Map-room.

The width of Kennedy Channel (a continuation of Smith Sound) is at 80° north lat. about 40 miles, but between latitudes 79° and 80°, Smith Sound expands to a width of something like 100 miles, this expansion being chiefly formed by a large bay on the east side. The south point of this bay, which I have marked A in the accompanying chart, runs far to the west in lat. 78° 30' (thus changing the direction of the Sound from nearly true north and south to N.E. and S.W.), and approaching within 30 miles of the west shore at the point B.

If there is, as I believe, a set or drift of current southward, the ice will first be pressed with great force—as Kane found to his cost—against that side of the bay of which A is the south point, and then it will be driven across to the west shore somewhere near B at the narrowest part of the Sound in a closely-packed and continuous stream of heavy floes hitherto found impenetrable.

Should this idea be correct, and there is something more than theory to support it, this obstruction will be a constant and not an occasional one as long as there is a supply of ice to the north.

If there is a large opening extending far to the west at the place marked C, we have another probable opposing element; for if the set of current runs eastward through it, we shall have an important addition to the Smith Sound supply of ice, in making the barrier of the “pack” more formidable. The opinion I express as to the direction of the currents is not wholly hypothetical, for we have proofs of an *almost constant* current (it is sometimes reversed by strong winds) setting southward down Baffin's Bay and Davis Strait; and this current can only be fed by Lancaster and Smith Sounds and other openings to the west and north.

The only hope of an “easy” passage up Smith Sound to a higher latitude than 78° 40' is the existence of Kane's “great open Polar Sea,” for if such sea does exist, there would be no ice to the northward to keep up the supply of this commodity in Smith Sound, which would in the summer months be cleared of its winter covering by the southerly drift I have already mentioned, and the Sound would, and probably will be, consequently free from ice in August. But this is opposed to both Kane's and Hayes's experience, whatever their expressed opinions about the large open sea may have been.

That Kane's man Morton saw a very considerable extent of open water is not to be doubted, also that it may be quite true that he saw no ice to the northward, although he put down a point of land (whether correctly or not it is difficult to say) seventy miles distant in that direction. Every one, however, must be aware—for it is not necessary to have been in the Arctic seas to acquire such knowledge—that when the temperature of the air is lower than that of the water, a vapour or haze is formed by condensation, which, although by no means dense when looking through a small extent of it, becomes so much so when the observer has to look through eight or ten miles of it, that any low object, such as floe ice, would be quite in-

visible at either of these distances, and the haze itself would give the appearance of a distant water horizon.*

The opinion that this open sea was of limited extent is, I think, further confirmed by what Mr. Morton states as a proof (as he thought) of its being "boundless" or very large. Morton says "that he remained for three days watching the open sea rolling in waves at his feet, and, although there was a strong breeze or gale blowing from the north all the time, not a single piece of ice" floated past to the southward.†

My interpretation of the above fact is quite the opposite to that of Morton, for I believe there was a barrier of fixed ice at no great distance to the north, hid from his view by the cause I have named, which prevented any ice driving south at the season of the year when Morton was there, I think in June.

I offer these opinions with much diffidence, for we have been recently told that all great Arctic authorities now agree as to the Smith Sound route being the best. When the subject was brought prominently to notice in 1865, the "great authorities" did not agree, there being about as many opinions on one side as on the other.

At that time, without the slightest pretence to being an "authority" in the matter, I looked rather closely into the figures on which the facts favourable to the Smith Sound route were founded, and finding these figures in several important instances erroneous, the facts themselves lost much of their value. JOHN RAE

* I use the term "water horizon" in opposition to "ice horizon," which exhibits a bright line easily recognisable by those who have once seen it.

† As I quote from memory, I give to the best of my belief Morton's meaning, if not his words.

THE TYPHOON OF 2nd SEPTEMBER, 1871

THE Typhoon in China of the 2nd September last, detailed accounts of which reached England by the last mail, and which included in its area of most active violence the island and vicinity of Hong Kong, affords to those interested in such natural phenomena an opportunity of observing their varied characteristics, that may possibly never occur again. The great centre of its efforts having been in a situation where elaborate observations could be taken regarding it both at sea and land, a vast amount of information has been collected on the subject, which throws more light upon these singular "freaks of nature" than has ever before been arrived at.

In treating on the subject, I shall in the first place point out the course which—after careful investigation—I believe the typhoon to have followed, and afterwards I shall state the evidences that I adduce in support of the theory which I have adopted. Before commencing, however, it may be as well briefly to illustrate the plan engraved. The names *Formosa*, *Siam*, *Onward*, *Mikado*, *Woodbine*, and *Anna Henderson* are those of six vessels which were on their way to and within a short distance of Hong Kong during the typhoon, and extracts from whose shipping reports are now before me. A portion of the continent of China is to the north of the plan. The town of Macao and the islands of Hong Kong, Lantau, and Lema are in their respective positions.

The course which was taken by the typhoon was nearly allied to a parabolic curve. I have not attempted to trace its source farther eastward than the position indicated by 22° 30' N. lat. and 116° 10' E. long., where it overtook the *Formosa* (see *a* in map), or to follow it beyond the point indicated by 21° 15' N. lat. and 115° 45' E. long., where it struck the *Onward* (see *f* in map) on its return from the West. This portion of its course is marked in the plan by a succession of dotted lines. Consequently my observations are confined to the proceedings of the typhoon within these limits. After passing the *Formosa*, it swept over Hong Kong, crossed the mouth of the Canton River, and continued its headlong career to the town of Macao. Approaching this point, however, it was met by a strong northerly gale, and turned towards the south, but again encountering opposition in the shape of a south-west gale, it returned towards the east, upsetting the *Mikado* and driving the *Onward* before it. Throughout its entire course it consisted of a comparatively narrow belt of wind.

So much for the statement of my theorem. Now for its proofs.

I assume that only three conditions are necessary to substantiate my argument:—

1. I must prove that the typhoon reached the various positions which I have indicated in the order actually laid down.
2. That it reached them at successive intervals of time.
3. That its greatest observed efforts were exerted on or in the vicinity of the line adopted by me, and not at any appreciable distance to the right or left of it.
4. That the two opposing gales, which I have described as occasioning the alteration in the course of the typhoon, did actually exist.

The first and second of these four conditions appear to be so intimately connected, that I think I cannot do better than consider them together. The earliest observations of the typhoon were made by the *Formosa*, which experienced its full force in the situation indicated in the plan between *a* and *b*. Both positions are accurately determined. The following is an extract from the shipping report: "On September 2, the barometer 29°30, experienced very heavy typhoon; during the typhoon the ship suffered some damage. At 4 A.M. on 2nd inst., barometer 29°25, blowing very heavy from east; at 12 noon, the same day, the wind moderated; at 2 P.M. on same made some

sail." The second series of observations was taken at Hong Kong (*c* in plan). Here I may quote from the register kept at Junk Island, near Hong Kong, during Saturday, September 2, and Sunday, September 3:—

September 2

Hour	Wind	Force	Barometer
1	N.N.W.	6	29'58
2	"	"	29'54
3	"	"	29'52
4	"	"	29'50
5	"	"	29'48
6	"	"	29'46

2	E.S.E.	11	29'25
3	"	10	29'30

—and so on, the barometer rising, as the gale decreased.

It will, of course, be remarked that the *east* wind was the veritable typhoon. This is clear from the fact of the barometer reaching its lowest point, and the force of wind

being the highest registered, at or about the hour when the vane pointed to the east. Now, to proceed in the same direction that the typhoon is following as far as the town of Macao (*d* in plan). No register, unfortunately, was preserved—at least, that has transpired—of the direction of the winds at Macao during September 2 and 3, but the barometrical readings were as follows:—

Date	Hour	Reading
September 2	12 Noon	29'705
"	3 P.M.	29'605
"	5 "	29'555
"	6 "	29'485
"	7 "	29'475
"	8 "	29'425
"	9 "	29'405
"	10 "	29'285
"	11 "	29'185
"	11'30 "	29'135
"	12 Midnight	29'095
September 3	1 A.M.	28'785
"	1'30 "	28'485
"	2 "	28'385*
"	3'30 "	28'885
"	4 "	29'035

Still, although no record has been preserved of the direction from which the wind came on this occasion, it is evident, from the nature of the injuries inflicted upon Macao, that it was the turning point or apex of: the typhoon. The effects bore a strong analogy to those of a cyclone or whirlwind, as will be seen from the following extract from the *Overland China Mail* of September 15:

"No less than three vessels, the *Vistula*, French *Edouard de Marie*, and a Dutch barque, have been wrecked in the roads. . . . Baron de Cercial's house on the point has been unroofed; the clock tower top has been blown down; and the façade of the San de Lorenzo Church has been torn off by the force of the wind." Continuing still farther round the course indicated by the

* At this time, between 9 and 11, the typhoon struck the island.

* At this time the typhoon struck the island.

dotted lines in the map, and omitting to take notice of the *Woodbine* and *Anna Henderson*, we arrive at the *Mikado*, whose situation (marked *e* on the plan), although not so clearly specified in the report as might be desirable, must, nevertheless, have approximated to that laid down, if we take into consideration the direction from which it was sailing (from Saigon to Hong Kong) and the time at which it arrived in harbour, viz., about four and twenty hours after the typhoon had passed over it. The shipping report is as follows:—"On midnight the 1st inst. (September) the barometer falling, wind increasing from the northerly, barometer falling rapidly. On midnight of the 2nd instant, the weather indicating a typhoon, began to take in sail; the wind continued increasing, the barometer still falling; at 8 A.M. on the (3rd)* instant took in the main topsail; at 11 A.M. till 2 P.M. blowing a very heavy typhoon, the ship lying on her beam end, the barometer 29'34. At 3 P.M. weather began to moderate, and the ship began to righten. At 8 P.M. on same day the weather again moderated, and we then commenced to make sail to Hong Kong; the wind rounded to E.S.E." (showing that it had been westerly or north-westerly during the gale). But the fullest and most minute account of the typhoon appears in the narrative of the *Onward's* adventures during its occurrence; and here, fortunately, I am able to repose the utmost confidence in the statements adduced, owing to a personal acquaintance of several years with the Captain and officers of that vessel. There is not the remotest difficulty in determining the position of Captain Whyte's vessel during the 2nd and 3rd September, the bearings and distances being quoted on all important occasions. The report runs thus:—"Current setting to S.W. $\frac{1}{2}$ W., 34 miles daily. September 2, at 6 P.M. (barometer 29'83), N.E., head of Lema Islands, bore N. by W. $\frac{1}{2}$ W., 15 miles distant; tacked ship and stood to eastward, wind at N. with a heavy easterly sea coming away, with all appearances of bad weather; midnight (barometer 29'70) wind N. increasing to a gale; reduced the ship to two topsails; 4 A.M. (barometer 29'59), wind still at N., gale still increasing with heavy sea from the eastward; 8 A.M. (barometer 29'39), strong and increasing gale, furlled all sails, and secured them with double gaskets, and made every preparation for a hard gale. September 3, at noon (barometer 29'15, still falling), wind N.W., blowing most terrifically with a fearful cross sea, ship pitching heavily, putting bowsprit and jibboom under water at times, and filling the decks with water; 4 P.M. (barometer 29'3), wind W., blowing harder than ever with thick rain; at 6 P.M. (barometer 29'10), wind W.S.W. blowing still most terrifically with a most fearful cross sea running; at 8 P.M. (barometer 29'20), wind S.W. inclined to moderate, sea still very heavy; midnight (barometer 29'39), wind at S., both wind and sea greatly down with all appearance of better weather; 6 A.M. (barometer 29'60), wind S.S.E., moderate breeze, made sail and squared away for port." The run of the ship from 6 P.M. September 2 till 4 P.M. September 3, I have represented by the line *l f*, as, although the course taken was supposed to be easterly, the strong current setting in a S.W. direction would certainly bring it down to the point *f*. Thus the ship in endeavouring to escape the typhoon ran right into it! Now what may be gathered from all these facts? That a terrific gale from the east struck the *Formosa* in the position indicated by *a* on the 2nd September at 4 A.M.; that it passed over Hong Kong (at *c* in map) between 10 and 11 the following night; that it reached Macao (*d* in map) at 2 A.M. on the morning of the 3rd, exhibiting such peculiar phases of character as would lead one to believe that it was revolving on its axis; that (after changing its direction) it overtook the *Mikado* in the position indicated

by *e*, at 2 P.M. on the 3rd September; and that finally it swept over the *Onward* in the position indicated by *f*, still coming from the west, at 4 P.M. the same day.

Hence I conceive that my first two conditions are proven.

The third is as easily disposed of. That the typhoon did not spread itself out to any great extent in a northerly direction is clear from the fact of Canton not having experienced its fury. There was a smart gale blowing on Saturday and Sunday; but the barometer did not descend below 29'40, and the typhoon was described there as being "insignificant." That it was not felt so far south as 21° N. lat. is evident from the shipping reports of the *Woodbine* and *Anna Henderson*, which make no mention of it. They speak of gales blowing hard from the N. and S.W., and culminating upon the evening of the 2nd of September; but it is apparent, from the tone of their descriptions, that they did not encounter the veritable typhoon. The *Woodbine's* report is as follows:—"2nd of September, about thirty miles from Lema Island, when encountered a heavy typhoon from N. to S.W., with heavy sea." The *Anna Henderson* says:—"Wind veering to N.; on the 2nd increased to a gale, splitting several sails; at 7 A.M. on same day blew away the main topsail, the gale continued up to 6 P.M., then began to moderate." Their courses after receiving the shock of the northerly gale are represented by *h i* and *j k*, and these cannot be far from the actual ones taken, as the positions *h* and *j* are determined from observations quoted in the shipping reports, and the ships having been small, with wind and current both dead against them, must have been driven in the directions indicated. Fortunate for them that it was so, for by this accident they escaped the typhoon altogether. With regard to the interior edge of the typhoon, it would be impossible to ascertain how far it extended; but that there was a region of comparative calm within its circumference is easily proved. The *Siam*, from Newchwang, a port in the north of China, when in 21° 30' N. lat. and 115° 15' E. long., experienced a gale, which, during the 2nd of September, went right round the compass, clearly showing that the ship was in the centre of the typhoon. But that the *Siam* did not feel the full force of the gale or anything like it is equally clear from the trifling notice taken of its effects. The date of this vessel's arrival in port leads us to believe that it scarcely altered its position during the gale; probably as the wind veered round it drifted northwards, as indicated at *g g* in the map. The shipping report states:—"1st of September, in lat. 21° 30' N., long. 115° 15' E., when experienced another heavy typhoon* from N.E. veering to N.N.W., and round to S.S.E., with very heavy cross sea, and much rain; on the 3rd inst. it began to moderate, wind from S. to S.S.E." I think therefore we may fairly gather that the typhoon's influence did not extend in any great degree to the right or left of the course laid down for it in my map.

Hence condition three is proven.

The fourth condition scarcely requires demonstration. The truth of it is apparent from the report of the wind at Hong Kong up to 3 P.M. on the 2nd of September, and that of the ship *Woodbine*, which occupied the most westerly position of any of the vessels, from whose accounts I have gathered my information.

It seems therefore reasonable to assume that the typhoon of the 2nd of September did take the course indicated by me, which is nearly that of a parabolic curve. Should such be the case, it goes far to prove that these eccentric phenomena have not a circular form, as has hitherto been imagined.

One of the most interesting facts that has been elicited from these investigations is, however, the indication that a space of comparative calm does exist within the circuit

* I have altered this from 2nd to 3rd as the typhoon could not have been "indicated" after it had actually occurred! The figure 2 was evidently a misprint.

* This shows in how qualified a sense the word "typhoon" must be taken in reading the *Siam's* report.

of a typhoon, a theory which has always been advanced, but, so far as I know, has never hitherto been substantiated by any actual observations. The case of the *Siam* is a strong argument in favour of the truth of such a theory, for in point of fact it may be said to have scarcely felt the effects of the typhoon at all.

Should any of your readers be disposed to sift the various evidences which I have adduced, the papers are in my possession, and access can be had to them at any time.

FRANK ARMSTRONG

NOTES

WE have received full intelligence of the English Eclipse Expedition from Mr. Lockyer, under date Galle, November 29. At that date the expedition had been detailed into various parties for service at different stations in Ceylon and the mainland; the instructions to these several parties are reprinted in another column. Mr. Lockyer, Dr. Thomson, and Captain Maclear were to observe at Ootacamund, Mr. Davis being detached to photograph at Gunote; Messrs. Abbay and Friswell were to go to Manantawaddy, Signor Respighi and Mr. Holliday to Poodacottah; while Captains Tapman and Fyers and Messrs. Moseley and Lewis were to proceed to Trincomalee. The Indian and Cingalese authorities and the officers of the *Misapora* and *Glaxova* had exerted themselves to the utmost to assist the expedition, and the Ceylon party acknowledge great obligation to Captain Fyers, the Surveyor-General. In another column will be found an account of the voyage out.

WE hear with great satisfaction that Mr. Edgar Leopold Layard, C.M.Z.S., has received the appointment of H.B.M. Consul at Para. Mr. Layard has already done good service to science in Ceylon and South Africa, and will now have the pleasure of investigating the fauna and flora of a third and not less interesting region. Before leaving England we understand that Mr. Layard will publish a new and revised edition of his work on "The Birds of the Cape Colony," which is now nearly ready for the press.

WE are informed that Mr. Leighton is preparing for publication a conspectus of all the Lichens hitherto discovered throughout the world, with diagnoses, &c., and also a second edition of the Lichen Flora of Great Britain, Ireland, and the Channel Islands, which will combine an Introduction, Glossary, and Index, and which, it is hoped, will be ready for the press early in 1872. The Glossary, &c., will be printed separately, so as to enable possessors of the first edition to purchase separately.

MR. T. K. SALMON, of Guildford, is making preparations to start on a collecting expedition to the highlands of the Columbian republic. Mr. Salmon's head-quarters will be at Medellin, in the State of Antioquia, whence he will explore the Cordillera of Quindin, and upper valley of the Cauca. Mr. Edwin Gerrard, jun., of College Street, Camden Town, acts as his agent, and will be happy to receive subscriptions in aid of the expedition.

WE are glad to hear that the well-known naturalist, Mr. W. T. Blanford, of the Indian Geological Survey, is appointed a member of the British expedition for the survey of the boundary between Persia and Beloochistan. Commencing on the coast of Mekran the party will pass northward to Seistan and Herat. In Seistan they will enter a most interesting region, of which the geology and zoology are quite unknown. The river Helmund, and Lake of Seistan, in which it loses itself, will certainly present many features eminently worthy of scientific investigation, of which no one is more qualified to take advantage of than the ex-geologist of the Abyssinian Expedition.

The recent death of Dr. Seemann, who for nine years has conducted the *Journal of Botany*, has caused a change of editor-

ship. A new (2nd) series will be commenced in 1872, under the management of Dr. Trimen, of the British Museum, for the last two years a sub-editor, with Mr. Baker, of Kew, who will continue to be associated with Dr. Trimen in the conduct of the new series. We are also requested to state that unavoidable circumstances will delay for a few days the publication of the January number.

THE Edinburgh papers record the death of Mr. J. B. Davies, assistant-keeper of the natural history section of the Museum of Science and Art in that city. Mr. Davies was appointed to his position in the museum, while it was in its old place in the College, by Edward Forbes during the brief period that gifted naturalist occupied the Chair of Natural History; and in the discharge of his duties he was as much distinguished by the extent and accuracy of his knowledge as by his readiness to assist all students of his science, and by his courteous bearing. In addition to his appointment in the museum, Mr. Davies held the lectureship on zoology in the Royal High School, was assistant-secretary to the Royal Physical Society, and an Associate of the Botanical Society. He was the author of a little manual of practical natural history termed "The Naturalist's Guide."

THE following have been elected office-bearers of the Edinburgh Botanical Society for the ensuing year:—President, Prof. Wyville Thomson, LL.D.; Vice-Presidents, Dr. M'Bain, R.N., Prof. Dickson, Mr. Buchanan, Dr. T. A. G. Balfour; Secretary, Prof. Balfour; Foreign Secretary, Prof. Douglas MacLagan; Treasurer, Mr. P. N. Fraser; Auditor, Mr. Tod; Artist, Mr. Neil Stewart; Assist. Sec. and Curator, Mr. John Sadler.

IN connection with the Gilchrist Education Trust, arrangements have, we understand, been made for the delivery at the Lambeth Baths of a series of lectures, chiefly of a scientific character. The names of Prof. Huxley and Dr. Carpenter are mentioned among the probable lecturers.

MM. DELAUNAY and Ch. St. Claire-Deville have presented to the French Academy of Sciences some further interesting notes of the cold of November and the early part of December. M. Delaunay remarks that the cold advanced, as is usually the case, from north-east to south-west. The minimum temperatures were recorded at Gröningen, in Holland, on Dec. 7 ($-10^{\circ}\text{C.} = 14^{\circ}\text{F.}$); at Brussels ($-12^{\circ}\cdot6\text{C.} = 9^{\circ}\cdot5\text{F.}$) on the 8th; and at Paris ($-21^{\circ}\cdot3 = -6^{\circ}\text{F.}$) on the 9th. This extremely low temperature appears to have been limited to a very small tract of country between Paris and Charleville. On the same day the temperature was above the freezing-point in Scotland as far north as Nairn, and in the greater part of England, falling only at Greenwich as low as $-2^{\circ}\cdot3\text{C.} (=28^{\circ}\text{F.})$. The severity of the frost was considerably mitigated at Paris on the 10th and 11th; but on the latter date it was again as low as $-22^{\circ}\cdot6\text{C.} (= -8^{\circ}\cdot5\text{F.})$ at Haparanda, on the Gulf of Bothnia, $-15^{\circ}\text{C.} (= 5^{\circ}\text{F.})$ at Stockholm, and $-14^{\circ}\cdot1\text{C.} (= 6^{\circ}\cdot5\text{F.})$ at St. Petersburg.

SOME of our readers will recollect the controversy which took place in the "Proceedings of the Zoological Society" and the *Athenæum*, some six months ago, respecting a tortoise's skull in the British Museum, upon which Dr. Gray had established a new genus and species, *Scapia falconeri*. Mr. Theobald maintained that this skull (received by the British Museum from the executors of the late Dr. Falconer) had originally belonged to one of the two typical specimens of Mr. Blyth's *Testudo Phayrei*, in the Indian Museum, Calcutta, and that consequently *Scapia falconeri*, Gray = *Testudo phayrei*, Blyth. Dr. Blyth maintained the contrary. We understand that the director of the Indian Museum has recently claimed the skull in question, and that it is now on its way back to Calcutta, so that the authorities of the British Museum must have given up their view of the question.

At a recent meeting of the Manchester Literary and Philosophical Society, Mr. John Hopkinson, B.A., D.Sc., detailed some experiments on the subject of the rupture of iron wire by a blow, the results of which are—1. That if any physical cause increase the tenacity of wire, but increase the product of its elasticity and linear density in a more than duplicate ratio, it will render it more liable to break under a blow. 2. That the breaking of wire under a blow depends intimately on the length of the wire, its support, and the method of applying the blow. 3. That in cases such as surges on chains, &c., the effect depends more on the velocity than on the momentum or *vis viva* of the surge. 4. That it is very rash to generalise from observations on the breaking of structures by a blow in one case to others even nearly allied, without carefully considering all the details.

We learn from the *Lancet* that all the English universities have now accepted the draft scheme for a Conjoint Examination Board, as proposed by the College of Physicians and the College of Surgeons of England, and that it only now remains to submit the matter to the standing counsel of the two latter bodies for their opinion as to the practicability of carrying out the scheme without in any way violating the provisions of their respective charters. It is pretty well known that in the case of the Royal College of Physicians no difficulty at all is apprehended. It is probably so with the College of Surgeons, but of this we have never had positive assurance.

ATTENTION has been called to the present disgraceful state of the fine mausoleum erected to the memory of Sir John Soane, in the cemetery of St. Giles-in-the-Fields, King's Cross. The tomb of the founder of the first art museum and architectural library in England is surely deserving of preservation. At present, however, its balustrades are broken, its marble capitals chipped, the inscription wilfully defaced, and the entrance filled with brick rubbish. We commend this state of things to all art students.

IN the current number of *La Philosophie Positive*, Nov.—Dec., 1871, M. Littré calls attention to the reorganisation of public education in France. "If we are ever," he says, "to have a public system guided by a sound general method, we must begin tentatively and experimentally with private effort;" he then adds, "As for ourselves, it is intended among the writers in this review to compose six treatises, one for each of the fundamental sciences, mathematics, astronomy, physics, chemistry, biology and sociology. They should be so subordinated one to another that each science should form an introduction to the next above it in the scale; they should also be so far restricted to what is of essential importance that the entire course might be mastered in a time compatible with the necessities of life; and complete enough to raise the student to the main level of positive knowledge." There has been a good deal of discussion, especially in this country, about the scientific value of Comte's classification of the sciences. Perhaps a practical experiment like the above is the best criterion of the question, and the wonder is that it has not been applied before.

AFTER unexpected delays, the new Coast-Survey exploring vessel, the *Hassler*, left Boston on December 4, bound for California *via* the Straits of Magellan. The *personnel*, which is under the scientific direction of Prof. Agassiz, and the plans of this expedition, have already been given.

Harper's Weekly gives the following account of the labours of Prof. E. P. Cope, of Philadelphia, mainly in the valley of the Smoky Hill Fork of the Republican River in Kansas, where, under the protection of an escort of seventy-five infantry, commanded by Captain Butler, and detailed by order of General Pope, he spent seventeen days in the diligent prosecution of his

labours. As is well known to American paleontologists, this region is one of the richest of the world in fossil remains of reptiles and fishes. Of these a large number of specimens were obtained by Prof. Cope, many of extraordinary magnitude, and some of them entirely new to science. More or less complete series were obtained of the bones of animals previously known only by a few fragments, thus supplying much better information as to their affinities and position in the system. Nearly the entire skeleton of a large fish, provided with teeth of immense power, was exhumed. This animal is to bear the name of *Porthetus molossus*; and its remains occurred in such abundance as to demonstrate that it must have been a characteristic and very formidable inhabitant of the cretaceous seas. Another discovery was that of a reptilian form related to or intermediate between the tortoises and serpents. The ribs of this animal were long and attenuated; but instead of being united in the carapace, as in the tortoise, remained separate possibly united by membrane. If built at all on the chelonian pattern the expanse would have been at least twenty feet. This is to be called *Protostega gigas*. During his explorations in 1870 Prof. Marsh ascertained the existence of a species of pterodactyl, or flying lizard, in the cretaceous strata of the West, and additional specimens of the same or another species were found by Prof. Cope during the expedition just referred to. The most gigantic reptiles met with by him this year were species of *Liodon*, *Polycotylus*, and *Elasmosaurus*. Of these *Liodon* was found most abundantly, and one specimen will probably prove to be the largest of all known reptiles. *Elasmosaurus* had the most massive body, and must have presented an extraordinary appearance, in consequence of the great length of its neck.

We have already referred occasionally to investigations prosecuted during the past summer on the great lakes of North America, into the fauna and physical condition of the deeper waters; and we find in the last number of *Silliman's Journal* a more detailed account of that portion of the work carried on in Lake Superior upon the U.S. steamer *Search*, under the direction of Gen. Comstock, of the Lake Survey, as reported by Mr. Sydney J. Smith, the zoologist of the expedition. The deepest water met with was 169 fathoms, the bottom being there covered, as in all the deeper portions of the lake, with a uniform deposit of clay or clay mud; and not the slightest trace of saline matter was detected in the water in any part of the lake. The temperature, everywhere below thirty or forty fathoms, varied very little from 39° F., although in August it varied at the surface from 50° to 55°. The fauna at the bottom was found to correspond to these physical conditions. In the shallow waters the species vary down to thirty or forty fathoms, after which the deep-water fauna begins, and the species appear to be uniformly distributed. The list of species is meagre, and the deep-water region is characterised rather by the absence of many of the shore species than by the presence of any peculiar class. The same crustaceans and marine forms met with in 1870 in Lake Michigan were also found here abundantly, together with the same species of *Pisidium*; and some of the crustaceans have so far been undistinguishable from those found in Lake Wetter, in Sweden. The detailed account, of which that in the *Journal of Science* is an abstract, appears in the report of the Chief Engineer of the army to the Secretary of War just presented to Congress (Report of American Secretary of War, vol. ii. p. 1020).

M. RAOULT states, in a paper read before the French Academy of Sciences, that cane sugar becomes transformed into grape sugar under the prolonged influence of light. Having dissolved 10 grammes of white sugar in 50 grammes of pure water, and boiled the solution for a few minutes, he placed equal portions in two white glass tubes, which were then hermetically closed. One was deposited in a dark place, while the other was exposed

to light. Five months afterwards the tubes were opened, and the contents of that which had been exposed to light gave the reaction of glucose.

A CORRESPONDENT of the *Madras Times* states that on the night of the 21st of October a remarkable meteor was seen at Trevandrum. It first became visible in the northern part of the sky, proceeding at a rapid rate and in a straight line, at an elevation of from 35° to 40° . It was visible for about four seconds.

A BRAHMIN astronomer at Surat has "predicted" that a terrible earthquake will be felt in some parts of the Bombay Presidency either in December or January next.

INDIAN papers state that during the first six months of this year as many as 183 tigers and cubs, 393 panthers and leopards, 203 bears, 281 wolves, and 188 hyenas, were destroyed in the Central Provinces at a cost to the Government of about 9,000 rupees (900*l.*). What a chance for any enterprising Zoological Museum!

We do not look for zoological statistics in the annals of trading companies; but there is one report that does afford material, that of the Hudson's Bay Company. There we see year by year the varying number of fur-bearing animals, given in a kind of Registrar-General's return of deaths. This year we do not see the details, but we learn there has been a great dearth of martens. A more serious ethnological fact is the great losses by small-pox among the Indians of the Saskatchewan district, being no less than 3,000. Throughout the Hudson's Bay district the Canadian Government is employed in regulating the Indians, but this no less forebodes their extinction; the more particularly as a railway is advancing to the Pacific, and steamers are to be placed on the Saskatchewan river and Lake Manitoba. Martens that are not killed and Indians that die mean reduced dividends to the Hudson's Bay shareholders and traders.

ON the Chilian map is to be placed Augol, just made a city. It is situated in lat. $37^{\circ} 42' S.$, long. $72^{\circ} 17' W.$, about three miles south of the head waters of the river Verzaro, and twenty-eight miles from Nacimiento. It was founded Dec. 6, 1862, and is a fortified place on the river Pecoiquen.

AT Santiago, in Chile, a zoological garden is to be formed in the Quinta Normal, or Normal Garden.

FROM recent accounts in the *Panama Star and Herald*, it appears the Panama pearl fisheries are now carried on by negroes, whose villages remind the traveller of Western Africa. The value of the fishery is about 30,000*l.* a year, but signs of exhaustion are now showing themselves. This is greatly attributable to the use of diving machines. A gentleman who owns one of the islands, having regulated his fisheries in the Ceylon manner, found that after two years' repose he got a larger crop. It is therefore suggested to regulate the Panama fisheries by law.

COAL has been discovered at Neblinto in Chile. That country is already largely engaged in the shipment of coal.

MUSCAT is now to be divided on the maps into two states, Muscat and Sohar, a once famous name.

THE diamond capital of Adamanta, at the Cape, is likely to become a permanent town. Its present settled and floating population is 20,000.

THE collector of Tinnevely, in Madras, reports that he has come to the conclusion, after his inspection of the Government Pearl Fisheries, that the oysters migrate every year when young.

THE miners of Copiapa in Chile have undertaken an exploration by subscription of the rich mineral resources of their Cordillera.

NUMERIC RELATIONS OF THE VERTEBRATE SYSTEM*

THERE are five (not four only) complete neural rib arches to the cranium of all vertebrate animals, to wit: (1) The condylar or sensitive belt with the condyle plates for side ribs, and the lower arch of the transversely bipartite occiput for its vault piece; (2) the petrosal or acoustic, containing the auditory nerves in its side beams (easily detected by removing the ear drum of Felines, &c.), and overarched by the interior belt of the occipital squama; (3) the parietal belt originally containing the true gustative of fixed tastes (sour, sweet, salt and bitter, the glosso-pharyngeal), in an incision; from which it is, however, soon crowded out by the internal carotid artery and the overlapping "acoustic rib blade." The next (4) is the optic or frontal, visibly succeeded, in fishes, by (5) the ethmoidal or olfactory vertebra. The rest of the cranium is formed by its "extremities" or prehensile appendages.

The same numeric law which pervades the entire vegetable kingdom reoccurs in the human fabric in a very marked manner.

The number of "radiating elements" in a coil or whorl, or of whorls in a cycle, or in cycles generally speaking, as in pine cones and flower buds, &c., are the following:—

1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, &c., progressing by the summation of the last two numbers.

The bands or parallel coils of flowers or scales in pine cones, sunflower discs, &c., embody these numbers successively, as they grow steeper and steeper, alternately on the right and left. The vertical bands, or columns, give the number of parts of the cycles involved.

The explanation heretofore given by me is this, that one element generates the other.

The elements are radial; they are bilateral rays, with a rift, so to speak, on the opposite side. It is there where, in a like manner as the seed-leaves of flowering plants produce prolific "ovules," new radial organs are developed from the preceding ones—laterally at alternate heights and towards the wider spaces.

This process, referred to the radial organs of plants in an early stage, will yield:—

1. The numbers of parts in question, successively.
2. The peculiar law of interpolations or of "divergence," viz.: by a number of interstices represented by the second preceding one of each cyclic number.

3. It will conclude the cycles, if it be supposed that the activity of each junior member depends on that of its progenital one; as in all cases of simple branch developments.

These numbers occur in like manner in the human frame, as follows:

Inclusive of the terminal (ossified or gristly) coccygeal element, we have exactly thirty-four spinal vertebrae.

Classifying nerves by their work, or "function," we find—

- 3 pairs of cervical nerves (neck).
- 5 pairs of brachial nerves (arms).
- 8 pairs of pedal nerves, composed of 3 crural (lumbar) and 5 ischiadic (sacral) ones.
- 13 pairs of nerves to the rump.
- 5 specific ones of the cranium.

34 in all; whereas the number of the spinal vertebrae, which inclose the spinal cord is exactly 21.

There are five pairs of "extremities," organised after a common plan: (1) the lower, (2) the upper, (3) the temporal (bearing the lower jaw for a "member"), (4) the palate-facial, with the upper jaw for its "member," (5) the opercular or hyo-tympanic one, forming the gill-lid in fishes or the tympanic ossicles in man; and the digital extremity of which is gradually converted into the (hand-like) crimped (external and internal) cartilages of the ear.

The five pair of hæmal arches of the cranium, i.e. the gill arches of fishes, are gradually transformed into the gill-ridges of the gullet, &c.

The main variation consists in the varying, but "cyclic" number of "rays," fingers, &c.; the varying cyclic number of their joints (1, 2, 5, 8, 13 respectively in a dolphin, with five carpi instead of eight, as in a man) and the varying cyclic number of "loose" ossicles, such as *carpals*, *tarsals*, *teeth*, &c. The number of spinal vertebrae is also variable, but not that of the cranial ones.

* Abstract of a Paper read at the Indianapolis Meeting of the American Association for the Advancement of Science, by Dr. T. C. Hilgard. Reprinted from the *American Naturalist*.

The vertebral blocks, as well as the ribs, are the product of the primitive axial series of (invertrebral) discs, which, when completely arrayed, each bear five branches, viz., two pair of hemal arches, two pair of neural arches, and a fascicle of parallel cleets, so to speak, which being cemented together, both in the front and rear, by the superficial ossification of the discs at either end, are fused into the block pieces, as found, e.g., in the young hog; the cementing slab covering the big neural rib head likewise, and not only the pentagonal prismatic block. The first disciform ossification we find in the corals, forming cribrate ethmoidal discs, such as the closely set "sigillate impressions" of the *Astræa*, and afterwards left behind as the coccyx, e.g., of *Byathophyllum*.

SIEMENS' DYNAMO-ELECTRIC LIGHT*

A SERIES of experiments was made last week at Sheerness, with a view of ascertaining the applicability of Siemens' dynamo-electric light to torpedo services in time of war. This scientific combination is produced, as its name signifies, by the application of excessively rapid motion generated from the fly-wheel of a steam-engine to a very powerful set of ordinary galvanic "coils" in connection with soft-iron magnets. The leather strap from a four-horse power engine, encircling a small gun-metal pinion, causes it to revolve with the extreme velocity of 1,600 revolutions per minute, inducing motion in an electric "bobbin" at the side of an apparatus consisting of several sets of strong insulated coils. A stream of electricity consequently passes through them. This stream is conducted to a second series of coils, larger and more powerful than the first, which are also in combination with a pinion revolving 800 times per minute, thus intensifying the stream as it passes through them to a very considerable degree. Both negative and positive currents are now alternately given off from another "bobbin" at the side of the second series of magnetic coils, to the train of insulated wires, which conveys them to the position from which the dynamo-electric light is to be exhibited. Here there is a delicately contrived apparatus for containing the carbon points, between which the light is to be generated, adjusted at the top of a tripod somewhat similar in construction to that of a surveying instrument. At the back of the two carbon points, and "slotted" vertically to admit of their holders passing through it, is a concave reflector of white polished metal, which collects the rays of light into a focus, and transmits them in any required direction by means of an adjusting hand wheel below. A minute aperture in the centre of the reflector, precisely behind the junction of the two carbon points, throws a representation of the flame upon a piece of opal glass in a frame fixed at the back of the reflector; and through the agency of another small hand wheel which causes the carbon points to approach or recede from each other, the flame can be reduced or intensified at pleasure, by simply turning the wheel, care being taken at the same time to keep a watchful eye upon the picture produced, as the withdrawing of the points to too great a distance from each other will extinguish the light. It should have been remarked before that ample means are taken by lubricating the electrical apparatus to counteract the evil effects which might otherwise arise from the excessive friction consequent on the rapidity of motion in the several parts.

The object of instituting the series of experiments which were made on Monday was to ascertain if it was possible to throw such a stream of light upon an enemy's working parties engaged in interrupting communications with a line of torpedoes at night, as would render them sufficiently conspicuous to be fired at and consequently driven off. The place selected was the new fort at Garrison Point, Sheerness. The engine and "coils" were erected in the enclosure of the fort, while the instrument itself was placed in one of the massive embrasures piercing its sides. No sooner was steam got up and the order given to turn ahead, than the burning noise of the machine indicated that electricity was being rapidly generated, sparks and stars of vivid blue light being given off at the various joints. Another instant, and a vivid stream of light shot across the sea to a number of ships lying in the offing at a distance of about two miles, lighting them up with the brilliancy and distinctness of broad moonlight. The effect was magnificent. Clouds of mists, rendered visible by the intensity of the rays shooting through them, rolled across the broad field of bright light from time to time, not, however, interrupting the view in their progress. By shifting the direction of the rays laterally, each object in turn came within the compass

of the portion of horizon rendered clear. In fact, it was sufficiently apparent that no objects of any appreciable size, such for instance as an enemy's boats, could come within a mile or more of one of Siemens' dynamo-electric instruments in operation without being rendered conspicuous to any battery in the vicinity, and consequently involving to themselves the most imminent danger. Hence the result of the experiments may be pronounced a success; whether, however, a corresponding effect might not be obtained by a succession of parachute lights thrown from a rocket or mortar is quite an open question.

PHYSICS

Note on the Spectrum of the Aurora

ON the evening of November 9 there appeared one of the most magnificent crimson auroras ever seen at this place. When first observed, at about a quarter before six p.m., it consisted of a brilliant streamer shooting up from the north-western horizon; this was continued in a brilliant red, but rather nebulous mass of light, passing upward and to the north. Its highest points were from 30° to 40° in altitude. A white aurora, consisting of bright streamers, appeared simultaneously, and extended round to the north-east.*

The crimson aurora was examined with the spectroscope at six o'clock. The instrument used was a single glass-prism spectroscope, made by Duboscq, of Paris. On directing the slit toward the brilliant streamer above mentioned, a bright spectrum was observed consisting of five well-marked lines. A millimetre scale attached to the instrument was then illuminated with a gas flame, the auroral lines being readily measured, even when the numbers on the scale were bright enough to be read distinctly. The sodium line was used to adjust the scale, being equally divided by the division 100; the width of the slit was about one millimetre. As thus arranged, the five auroral lines, beginning at the red end, had the following positions:—Scale-Nos. 90, 110.5, 130, 138, 149. The brightness of the lines was, following the above order, 3, 1, 5, 2, 4, the second line from the red end of the spectrum being the brightest. The line marked 90 and the one marked 110.5 were sharp and well defined; the others were all nebulous on the edges. Before the measurements were completely verified by a second comparison, the crimson aurora entirely vanished, having endured less than half an hour. In the white aurora which remained, the spectroscopy showed four of the five lines given; the crimson line alone was absent. The measurements are exact to half a division of the scale.

To determine the approximate wave-lengths of these lines, comparison was made both with certain metallic lines and with the lines of the solar spectrum. On the scale of this instrument the metallic lines employed read as follows:—

Ka 63, Lia 79, Sr 80, H(α) 82, Caa 91, Sra 96, CaB 113, H(β) 146.5, SrB 163, CsB 165, Caa 167, Rba, & B 200, Kβ 218.

The Fraunhofer lines measured as follows:—

a 70.5, B 76, C 82, D 100, E 124.5, b 130, F 146.5, G 189.

Direct interpolation was used in comparing the wave-lengths of the auroral lines with those given above, the wave-lengths of the Fraunhofer and elemental lines being taken from Gibbs's tables (Amer. Jour. of Science and Arts, II. xliii. 1, xlvii. 194). This method was believed capable of giving results as close as the instrumental measurements. In this way the wave-lengths of the five auroral lines were obtained, as given in the following table:

Line.	Scale number.	Wave-length.	Auroral lines.	Other measurements.
B	76	687		
C	82	656		
(1)	90	623	623	627 Zollner.
D	100	589		
(2)	110.5	562	562	557 Angström.
E	124.5	527		
(3)	130	517	517	520 Winlock.
δ	138	517		
(4)	138	502	502	
F	146.5	486		
(5)	149	482	482	485 Alvan Clark, Jr.
G	189	431		

* Professor Newton informs me that he observed an equally brilliant red patch of auroral light in the north-east, five or ten minutes earlier. Since the lower end of the red streamers was much lower than that of the white, it would seem as if the red were seen through the white, the red being most remote.

* Reprinted from the *Times*.

In this table, column 1 gives the auroral and the Fraunhofer lines; column 2, the number of these as measured upon the scale of the spectroscopic use; column 3, the wave-lengths of these lines obtained as above stated; column 4, the wave-lengths of the auroral lines, given by themselves; and column 5, the wave-lengths of what I assume to be the same lines, with their wave-lengths as measured by the observers mentioned.

The point of particular interest in this observation is the fact that the line (4) of wave-length 502 is not laid down in any authority accessible to me as having been observed in the auroral spectrum. Indeed, no previous observer, so far as I know, has seen any auroral line between the Fraunhofer lines *b* and *F*. Professor C. A. Young (*Journal of Science and Art*, III. ii. 332, Nov., 1871) gives two lines—Nos. 56 and 57, or 1866.8 and 1870.3 of Kirchhoff—observed by him in the sun's chromosphere and also by Rayet in the eclipse of 1868, one of which may coincide with this fourth auroral line.

New Haven, Nov. 13

GEORGE F. BARKER

SCIENTIFIC SERIALS

THE *Geological Magazine*, Nos. 86–89, August to November 1871. This valuable magazine continues to furnish us every month with important and interesting articles upon subjects belonging to the various departments of geology. In the first number now before us we find an interesting paper on volcanoes by the editor, Mr. H. Woodward, and a particularly valuable article by Mr. J. W. Judd on the anomalous mode of growth of certain fossil oysters. In the latter, which is illustrated with a plate, the author notices those oysters from various secondary deposits, in which the shell has acquired throughout the peculiar sculpture of some ammonite, *Trigonia*, or other shell, to which its lower valve has adhered during growth.—In the September number the most interesting paper is Mr. Woodward's description of a new Arachnid from the Dudley coal-measures. This animal, to which the author gives the name of *Eophrynus Prestivicii*, is most nearly allied to the existing genus *Phrynus*, and the specimen is remarkable for the beautiful preservation of the casts of both surfaces.—Among the contents of the October number we must call particular attention to Dr. Murie's article on *Sevatherium*, in which the author discusses the characters of that most remarkable animal, which he regards as most nearly allied to the Saiga antelope, the latter being placed by him at the central point of ramification of the hollow-horned ruminants, and leading from the ruminants towards the Pachyderms through the Tapir. This valuable memoir is illustrated with two plates, one representing the skeleton of the animal, the other giving an ideal restoration of the living aspect of the male, female, and young of this gigantic ruminant.—The November number opens with a biographical notice (with a portrait) of Sir Roderick Murchison, followed by a shorter one of Mr. Charles Babbage. The other articles contained in it are on relics of the Carboniferous and other old land-surfaces, by Mr. Woodward; on the prospects of coal south of the Mendips, by Messrs. Bristow and H. B. Woodward; on the futile search for coal near Northampton, by Mr. S. Sharp; and on the Foraminifera of the Cretaceous rocks, by Messrs. T. Rupert Jones and W. K. Parker.

THE *Journal of Botany* for November commences with an interesting contribution to historical botany, in a paper read by the late Robert Brown before the Edinburgh Natural History Society in 1792 on "The Botanical History of Angus" never before printed. It was probably his first contribution to botanical science, having been written when he was about eighteen years old. Prof. Thistleton-Dyer contributes some observations on "Fungi parasitic upon *Vaccinium Vitis-Idæa*," and Mr. A. W. Bennett "Further observations on Protandry and Protogyny," in continuation of his previous researches on this subject. Mr. T. A. Briggs has a note on an undescribed species of *Rubus*, and the remainder of the number is filled up with short notes, abstracts, extracts, and reviews.

The number for December opens with the commencement of a paper by Mr. J. G. Baker "On the Botany of the Lizard Peninsula." Although this district is well known to botanists as the habitat of many very rare and local plants, yet no detailed account has yet been published of the flora of this portion of Cornwall. From the idea that many plants very common in other parts of England would find their limit short of this south-

western extremity of the island, a list is here given of every flowering plant observed during a three days' visit, accompanied by general remarks on the peculiarities of the flora, both in what it includes and in what is absent from it. The only other original paper of importance in the number is a new arrangement by the Rev. J. C. Lee of the English species of the extremely difficult genus *Salix*.

Journal of the Royal Geological Society of Ireland, Part I, vol. iii. new series (vol. xiii.), has just been published. It contains besides the Report of Council for 1870–71, J. Emerson Reynolds on two remarkable Crystals of Galena; G. H. Kinahan, additional notes on Foliation, and supplementary notes on some of the Drift in Ireland; R. G. Symes, on the Geology and extinct Volcanoes of Clermont, Auvergne—plates i. ii. iii.; W. H. Baily, on the genus *Platyrhynchus*, and a new species—plate iv.; M. H. Ormsby, Analysis of some Granite Rocks from India, and of their constituent minerals (1668); Edw. T. Hardman, Analysis of Trachyte Porphyry from Tardree near Antrim, and on the Analysis of a Limestone compared with that of the same rock where it is in close proximity to a Doloritic Dyke; R. C. Titchborne, note on the Geological Formation of some of the Tiroxides.

Journal of the Chemical Society, October.—This number does not contain any papers originally communicated to the Society. The abstracts of foreign papers, however, occupy nearly 100 pages, and comprise many subjects of interest. The importance of the work done this way by the Chemical Society can scarcely be estimated; the journal must now be of great value not only to the chemist, but also to the physicist, physiologist, and to the chemical manufacturer, for many papers in these subjects are abstracted fully. An abstract of M. Berthelot's paper on the heat evolved in the formation of organic derivatives of nitric acid is very interesting. It is shown that in the formation of nitroglycerine, a very small amount of heat is evolved, as compared with that evolved in the formation of gun-cotton or nitrobenzene. This will account for the ready decomposition of the former, and the formidable effects produced by its decomposition. Amagat has experimented on the compressibility and dilatation of sulphurous and carbonic anhydrides; he finds that they first begin to act as perfect gases at a temperature of 250° C. Several of the abstracts contained in this number have already been noticed in these pages. One of them deserves especial notice, by Friedel and Ladenburg, on silicopropionic acid; this body is the first in which the group CO₂H contained in organic acids has been replaced by the corresponding group SiO₂H. Amato has obtained a curious compound, glucosoposphoric acid, the sodium salt of which has the composition C₆H₁₁O₇Na₂PO₄. Waage has published a paper on the use of bromine in chemical analysis, in which he points out that this reagent can be substituted with advantage for chlorine in many instances; it is very useful in decomposing pyrites, the whole of the sulphur being easily oxidised. We find an abstract of Bischof's paper on Fire Clays, which appears to deal very practically with this most important subject.

THE last just issued of the *Transactions of the Linnean Society*, completing vol. xviii., contains three papers, of two of these, "Revision of the Genus *Cassia*," by Mr. G. Benthams, the president, and "Contributions to the Natural History of the *Passiflora*," by Dr. M. T. Masters, abstracts have already appeared in our columns. The remaining paper, "Notes on the Reptiles, Amphibia, Fishes, Mollusca, and Crustacea, obtained during the Voyage of H.M.S. *Nassau* in the years 1866–69," by Dr. Cunningham, contains descriptions of several new species collected and named by the naturalist to the expedition, and notes on the habits, localities, and characters of many other species. All these papers are illustrated by plates.

The first part of Volume xviii. is also published, consisting of only a single paper, Dr. Triana's monograph of the *Molostomacæ*. After some general remarks on the order, and on each of the genera comprised within it in French, follows an enumeration of the species, with the synonymy, references to type specimens in the principal herbaria, and fresh descriptions of new or badly-described species. It is illustrated by seven plates.

THE *Bulletin of the Royal Academy of Sciences of Belgium* for September and October, 1871 (Tom. xxxii., Nos. 9 and 10), contains but little scientific matter.—M. J. C. Houzeau communicates a description of a method of measuring directly the

distance of the centres of the Sun and of Venus during the transits of that planet.—M. P. J. Van Beneden describes a new Sirenian from the Rupelian stage. The remains of this animal were obtained at Elisloo, near Maestricht, and consist of a portion of the cranium, one dorsal vertebra, and a series of seven caudal vertebrae. These are described and figured by M. Van Beneden under the name of *Crasitherium robustum*; he regards it as more nearly allied to the *Stelleria* than to the Manatees and Dugongs. M. Van Beneden also notices the occurrence at Basel near Rupelmonde of a nearly complete skeleton of a Sirenian in brick-work, and remarks upon the constant association of remains of *Squalodon* with those of Sirenians wherever the latter have been found in Europe. He also notices some points in the osteology of living Sirenia.—M. E. Van Beneden gives us a note on the preservation of the lower animals, in which he recommends the employment of solutions of osmic acid and picric acid for the preservation of the more delicate forms of animal life, such as the Medusae, Ctenophora, &c. According to him these processes are most successful.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 21.—“Contributions to the History of Orcin.—No II. Chlorine and Bromine substitution Compounds of the Orcins.” By John Stenhouse, F.R.S.
“Note on Fucosul.” By John Stenhouse, F.R.S.

Mathematical Society, December 14.—Dr. Spottiswoode, president, F.R.S., in the chair. Mr. K. Freeman, of St. John's College, Cambridge, was elected an ordinary member, and the following gentlemen foreign members of the Society:—Dr. Clebsch, M. Hermite, Prof. Cremona, Dr. Hesse, and Prof. Betti. Dr. Sylvester explained the methods he had employed in his paper, “On the theorem that an arithmetical progression which contains more than one contains an infinite number of prime numbers.” The communication was limited to the case of arithmetical progressions proceeding according to the common difference, 4 or 6. The method employed appears to differ fundamentally from Dirichlet's method (Berlin Transactions, 1837). [In the account of Dr. Sylvester's previous communication to the Mathematical Society, given in NATURE, Nov. 23, p. 75, at line 18 from the commencement of the paragraph, for *intention* read *induction*, and at line 20 from the foot of the page, for the words *the magnitude read the order of the magnitude*.] Prof. Cayley and H. J. S. Smith took part in a discussion on the subject.—Prof. Clifford next spoke with reference to a paper he is preparing for the society.—Prof. Cayley then drew attention to the question of the determination of the surfaces capable of division into infinitesimal squares by means of their curves of curvature. It was shown by M. Bertrand that in a triple system of orthotomic isothermal surfaces each surface possesses the property in question, of divisibility into squares by means of its curves of curvature. But in such a triple system each surface of the system is necessarily a quadric. There is nothing to show that the property is confined to quadric surfaces, and the question of the determination of the surfaces possessing the property appears to be one of considerable difficulty, and which has not hitherto been examined.—Mr. S. Roberts exhibited a thread model of a homographic transformation of the developable surface which circumscribes a system of compound quadrics. The surface is generated by planes touching an ellipse at a constant inclination, and its equation is obtained by writing $x^2 + y^2$ for z^2 in $\phi(x^2, y^2, z^2) = 0$ representing the plane parallel of an ellipse.

Anthropological Institute, December 18.—Dr. Charnock, president, in the chair. Lord Dunraven, Dr. John Best, and Mr. J. Kempe were elected members. A paper was read by Mr. Joseph Kaines on the “Anthropology of Auguste Comte.” The sources of the paper were to be found in chapters on “Biology” and “Fetichism” of M. Comte's *Philosophie Positive* and in the *Politique Positive*. The paper itself aimed to show that the differences between man and the rest of the animal kingdom were not so great as they were usually represented, nor in fact were they so numerous in their resemblances. Treating man as the head of the zoological series, it argued that his dominion over animals was from primitive times (and is now) a moral dominion rather than intellectual, and it concluded, that in so far as external nature was used by man for

moral ends, it was rightly used, and that the intellect found its true work in directing his affective nature to moral purposes and relationships.

Linnean Society, December 21.—Mr. G. Benthall, F.R.S., president, in the chair. “On the Anatomy of the American King-Crab (*Limulus polyphemus*, Latr.),” by Prof. Owen, F.R.S. The author, referring to anatomies of existing species of animals elucidating the type of structure of large extinct groups—as that of *Apteryx* in reference to the *Diornithidae*; of *Protoperis* in relation to the notochordal, protochordal Cyclogonoids of palaeozoic beds; of *Nautilus* as the representative of the constructors of extinct chambered and siphonated shells; of *Orbicula*, *Discina*, and *Terebratulina* in like relation to extinct *Brachiopoda*—stated that, in reference to the Trilobite Crustacea, he had once doubted whether *Scolis* or *Limulus* would reflect most light on the internal structure of those ancient forms of the class. But, in the 14th lecture of the Hunterian Course of 1843, published in April of that year, appreciating the importance of the character by which the Xiphosures and Trilobites agreed in differing from *Malacostraca*, viz., in the numerical formula of segments, he decided to take *Limulus* in hand. Isopodal tendencies in Trilobites indicated, however, their more generalised character, and continued palaeontological research led to the postponement of the original purpose, until the subsequent discoveries of a palaeozoic group of Crustacea, due mainly to the labours of Salter, Huxley, and Woodward, decided the author no longer to delay the present communication, in view of its more special bearings upon the *Merostomata* of the last-named carcinologist. Of the external characters of *Limulus* but little was left to describe. The author accepted the evidence of the homologies of the three divisions of the body adduced by Dana, Spence Bate, and Woodward as outweighing that which influences V. der Hoeven. The “cephalothorax” of the latter author was the “cephalon,” the second division was, not the “abdomen,” but the “thorax,” of the later carcinologists. The determination by the latter of the articulated appendages of the foremost division of the body of *Limulus* was also adopted. But as that division includes not only the brain, organs of sense, mouth, and manducatory instruments, but also the stomach, liver, major part of the heart, and genital organs, together with a long tract of the ventral ganglionic neural chords or centres, the author proposed to speak of it as the “cephaloteron,” the succeeding division as the “thoracoteron,” for the spine-shaped part he adopted Spence Bate's term of “pleon.” In the description of the cephaloteron, its modifications enabling it to act effectively as a burrowing digger or spade were dwelt upon, and the modifications of the hind border which articulates with the thoracoteron were pointed out, showing that whilst by coalescence it was part of the foremost division in all its formal characters, more especially its upper pair of entapophysal pits and under pair of coalesced lamelliform appendages, it belonged to the series of lamelliferous segments constituting the thoracoteron. The author then proceeded to give a detailed account of the muscular system of *Limulus*, and concluded this third section of the paper, by condensing notes made by Mr. Lloyd, of the Crystal Palace Aquarium, on the movements of living *Limuli* in captivity, and those made by Mr. Lockyer in New Jersey on the *Limulus polyphemus* in its native seas. The reading of this memoir will be continued at a subsequent meeting of the Linnean Society.

MANCHESTER

Literary and Philosophical Society, November 28.—Dr. J. P. Joule, F.R.S., vice-president, in the chair. “Encke's Comet and the Supposed Resisting Medium,” by Professor W. Stanley Jevons. The observed regular diminution of period of Encke's comet is still, I believe, an unexplained phenomenon for which it is necessary to invent a special hypothesis, a *Deus ex machina*, in the shape of an imaginary resisting medium. I cannot be sure that the suggestion I am about to make has not already been made, but I have never happened to meet with it; and therefore I venture to point out how it seems likely that the retardation of the comet may be reconciled with known physical laws. It is asserted by Mr. R. A. Proctor, Prof. Osborne Reynolds, and possibly others, that comets owe many of their peculiar phenomena to electric action. I need not enter upon any conjectures as to the exact nature of the electric disturbance, and I do not adopt any one theory of cometary constitution more than another. I merely point out that if the approach of a comet to the sun causes the development of electricity arising from the comet's motion, a certain resistance is at once accounted for.

Wherever there is an electric current, some heat will be produced and sooner or later radiated into space, so that the comet in each revolution will lose a small portion of its total energy. In the experiments of Arago, Joule, and Foucault, the conversion of mechanical energy into heat by the motion of a metallic body in the neighbourhood of a magnet was made perfectly manifest. If then there is any magnetic relation whatever between the sun and the comet, the latter will certainly experience resistance. The question is thus resolved into one concerning the probability that a comet would experience electric disturbance in approaching the sun. On this point we have the evidence now existing that there is a close magnetic relation between the sun and planets. If, as is generally believed, the sun-spot periods depend on the motion of the planets, a small fraction of the planetary energy must be expended. I find, indeed, that a very brief remark to this effect was given in the memoir of the original discoverers of the relation, namely, Messrs. Warren De La Rue, Balfour Stewart, and B. Loewy. At p. 45 of their *Researches on Solar Physics* they add a small note to the following effect: "It is, however, a possible inquiry whether these phenomena do not imply a certain loss of motion in the influencing planets." As I conceive, no doubt can exist that periodic disturbances depending upon the motions of bodies must cause a certain dissipation of their energy; for if stationary the constant radiation of the sun could not produce any periodic changes, unless the sun were itself variable. Is there not then a reasonable probability that the light of the aurora represents an almost infinitesimal fraction of the earth's energy, and that in like manner the light of Encke's comet represents a far larger fraction of its energy? It is also worthy of notice that the tail of a comet is usually developed most largely at those parts of its orbit where the rate of approach or recess is most rapid, and where the electric disturbance would be correspondingly intense. I do not, of course, deny that the resisting medium may nevertheless exist, or may by other observations or experiments be made manifest. But I hold that so long as other physical causes can be pointed out which might produce the same effect, it is quite unphilosophical to resort to a special hypothesis. Encke's comet ought not to be quoted as evidence of the existence of such a medium until electric disturbance is shown by calculation to be insufficient to account for the observed diminution of period.

LIVERPOOL

Geological Society, November 14.—Dr. Ricketts, president, in the chair. Mr. T. Mellard Reade, C.E., on the "Geology and Physics of the Post-Glacial Period, as shown in the Deposits and Organic Remains in Lancashire and Cheshire." The paper was largely illustrated by maps and sections. The author's views are summarised in the following conclusions:—1. That since the glacial period there are distinct evidences in Lancashire and Cheshire of three periods of depression or downward movement, and two periods of elevation or upward movement. There may also have been a period of elevation and a land surface previous to any of these movements, but posterior to the true glacial times. 2. That the first period of depression, which was the greatest, submerged the land to a minimum of 1,500 feet below its present level—in Wales at least—and was doubtless general. The post-glacial shells of Moel Tryfan and those by the Ribbles, indicating ancient beaches, belong to this period. During this time, and the re-emergence of the land, what the author termed the "washed drift sand" was eliminated from, sorted, and reformed out of, the boulder drift, and scattered over the country, but has since been much denuded by atmospheric and aqueous or sub-aerial influences above the 25 feet contour, and by sub aërial and submarine denudation below that line. 3. A re-emergence of the land took place, and a land-pause favourable to growth occurred, during which time the "inferior peat and forest beds," or sub-terrene land surfaces, were formed. At the period of pause the land would be higher than now, but the vertical extent of this movement the author purposed investigating hereafter. 4. A second period of subsidence again followed, and a pause occurred at or about the 25 feet contour line. "The Formby and Leasowe marine beds" were now laid down. 5. A second or latest vertical upward movement followed, elevating the Formby and Leasowe marine beds, upon which now grew the forest trees, the remains of which assist to form the "superior peat bed" extending along the coast margin from the river Douglas to Bootle in Lancashire, and from the Mersey to the Dee in Cheshire, and remains of which are found as high up the river Mersey as Garston and Warrington. 6. The third or latest downward movement now took place, and during this time the

river bed at Crossens was silted up, as also the Garston Creek. The drainage was obstructed, and the beds of marine silt intercalated in the peat. The tidal silt overlying the superior peat bed by the Douglas, the Alt, and the Birket, the silt which overlay the peat bed of Old Wallasey Pool, and that in which the vertebrae of a whale, now in Brown's Museum, were discovered at the North Docks, and all the deposits to which the author confined the term recent, belong to this period, in a pause of which we are now living. 7. That the whole of these movements were uniform over a far more extensive area than the author has investigated, he has not the shadow of a doubt. That post-glacial movements were slow is almost universally admitted, and from these the inference is obvious that the time which they measure compared with the historical period is so vast that it is difficult to form an adequate conception of it.

NORWICH

Norfolk and Norwich Naturalists' Society, October 31.—Mr. J. E. Taylor read a paper on "The Origin of the Norfolk Broadlands and Meres." With regard to the former, Mr. Taylor propounded the theory that the depressions, so-called, were owing to the influence of ice in remote ages, and that the basins thus scooped out had been since filled up by the growth of peat and the soil brought down by floods. His views were supported by an elaborate essay upon the probable condition of the European continent at the close of the glacial epoch, and the alterations effected by "the last geological change in its physical scenery and geography," as illustrated by the deep lakes of "Switzerland, Scotland, Cumberland, &c., hollowed out of the solid rocks by glacier action." He specially referred also to the great similarity in the physical aspect of the Dutch coast as compared with the Broad district of our eastern counties. Broadlands, he remarked, were distinguished from meres by being always in connection with rivers, and having a chalky bottom, more or less filled in with deposits of mud. Meres, on the contrary, in their physical characters, presented an almost entire separation from rivers and streams, "and the fact that they usually lie in the upper boulder clay, and therefore at a considerably higher level than the broads. The water supply of meres was simply the storage of wet seasons." The number of broads on the Bure and its tributaries, amounting in all to twenty-two, as compared with but four on the Yare, he attributed to the former stream having an average breadth of 150 feet, and the latter of only 100 feet. The formation of Diss Mere he considered due to glacial action, "as the neighbourhood abounded in evidences of such phenomena."—Mr. J. H. Gurney, jun., exhibited a male specimen of White's Thrush (*Orocincla aurora*), killed on the 10th October last, by Mr. F. Barrett, in a marsh at Hickling, and exhibited by permission of the Rev. J. Micklethwaite, for whose collection it is being preserved by Mr. T. E. Gunn. Mr. Gurney pointed out the distinctions between the closely allied genera of *Orocincla*, *Turdus*, and *Merula*, and made some remarks on *O. aurora* as a British species. It is, he said, the *Turdus Whitei* of Egton, and of Yarrell's "British Birds," so called after the well-known naturalist of Selbourne, and has been killed in six or seven instances in this country, the specimen exhibited being the first recognised as occurring in this country. It is found in China, and is said to have been met with in Siberia.—Mr. Barrett exhibited specimens of *Zygaena exulans*, a Swedish moth recently taken in Scotland.

DUBLIN

Royal Irish Academy, December 11.—Prof. Henry Hennessy, F.R.S., vice-president, in the chair. Prof. Robert S. Ball read two notes on applied mechanics. In the first note it was demonstrated that in whatever manner a figure moves in a plane, a number of points, lying on the circumference of a circle, are any instant in points of inflexion of the curves which they describe, and that the points of the circle are at points the tangent to which meets the curve in four consecutive points. These theorems embrace what are known in mechanics as the parallel motions. The second note contained an elegant geometrical construction by which the consecutive points of contact of two curves are determined.—The Secretary then read a paper by Mr. Hodder M. Westropp, in which the writer stated that he had abandoned his former theory that the Ogham inscriptions had a Danish origin, and now suggested that after all the learned interpretations that had been attempted of their meaning, they were nothing more than notches made to mark the number of cattle possessed by the owner of a plot of land at the annual division which took place under the ancient Brehon

laws of Ireland. It was simply a rudimentary scoring of numbers, such as had taken place amongst all nations in the earliest stages of civilisation. There was no substantial reason for attributing to the Irish, who, even at the time of Giraldus Cambrensis, had scarcely emerged from barbarism, the formation of an alphabet, and the attempts to decipher the inscriptions by attributing to them an alphabetic character were simply absurd. Dr. Ferguson, Q.C., said he was sure that if Mr. Westropp knew anything of the circumstances in which these inscriptions were found he would not have put forward such a theory. One of the very examples to which he referred in his paper proved the inaccuracy of his statement that these stones had not been found in connection with gravel. It was quite evident that in his illustrations he had worked from very imperfect copies, for his illustrations misrepresented the inscriptions. This was a case of a wild theory started without a fact being adduced in support of it.

Royal Geological and Zoological Societies of Ireland.—A joint meeting of these societies was held on Wednesday, the 13th of December, 1871, William Ogilby, M.A., F.G.S., in the chair. W. H. Bailey, F.R.S., read some additional notes on the Fossil Flora of Ireland. The author first described a new fossil plant from shale in the carboniferous limestone of Whitestone Quarry, near Wexford, under the name of *Filicites plumiformis*. He then gave the results of his examination of the collections made from upper Old Red sandstone strata at Kiltoran, Co. Kilkenny, which collections had excited considerable attention among the Continental and American botanists, and brought forward some strong facts to prove that the Irish palæontologists had not misled Prof. Heer, as stated by Mr. Carruthers at a recent meeting of the London Geological Society.—Prof. Traquair read some notes on the genus *Phanerophytion*.

VIENNA

I. R. Geological Institution, November 21.—The Director, Fr. Ritt. v. Hauer, read the anniversary report on the progress made by the Institute. The surveys were occupied in the course of the last year on two different regions; the military frontier, where the geological maps of the country between Brod in Slavonia, and the shore of the Adriatic were finished, and Tyrol, where parts of the crystalline central mountain region and of the northern limestone ranges were surveyed. At the request of private proprietors, the members of the Institute were occupied besides with particular inquiries as to the nature and extent of coal-seams, strata and veins of ores and other useful minerals in almost all parts of the empire, and a very accurate examination of the rocks which are to be perforated by the Arlberg Tunnel, between Tyrol and Varalberg, was made by M. H. Wolf. In the museum of the Institute the larger collections of minerals from the different mining districts of the empire were completely re-arranged, and a magnificent collection of fossil Mammalia, from the tertiary brown coal of Eibiswald in Styria, was exposed under glass. More than forty different persons have contributed by donations to the increase of the various collections. In the Chemical Laboratory more than 100 analyses and assays have been performed for about fifty parties. A new arrangement of the library was finished in the course of the year; with the end of 1870 it numbered 6,500 different works, with about 16,500 volumes; in the first ten months of 1871 the increase amounted to more than 12,000 volumes. The collection of Maps (besides those which were made by the Institute itself) consisted, at the end of 1870, of 2,850 sheets, and has since increased by nearly 300 sheets. The publications of the Institute were enlarged by a new periodical, the "Mineralogischen Mittheilungen," which is edited by Dr. G. Tschermak, the director of the Imperial Mineralogical Museum; they appear separately as well as in the form of a supplement to the "Jahrbuch." The publication of the memoirs ("Abhandlungen") of the Institute, which had been interrupted, was also recommenced this year by the publication of two memoirs: one by Dr. Neumayer, "On the Cephalopods of the Jurassic Beds of Balin, near Krakau;" the other by Dr. Bunzel, "On the Vertebrata of the Cretaceous Formation of Grünbach in Austria." Of the general geological map of Austria, edited by Fr. v. Hauer, appeared sheet No. 3 (the northern Carpathians), and the printing in colours of sheet No. 7 (the Hungarian plain) was finished. Dr. Neumayer noticed the discovery of the salt formation in the valley of Hall in Tyrol, at a point far below the salt mines now being worked. Here the mining work would meet with considerably less difficulty,

arising from the great height of the fold mine (5,000 feet above the level of the sea) the access to which in winter time is always dangerous, often even impossible.—Mr. Carl v. Hauer read a note on a very successful boring for coal in the tertiary basin near Fohnsdorf in Styria. On the northern edge of this basin, many years since, a large seam of coal had been worked. The bore-hole had been opened in the midst of the basin, 300 fathoms from the nearest point of the mine. At the depth of 155 fathoms the coal was reached in two seams, having together a thickness of 5½ fathoms. This discovery is of great importance for the industry of Upper Styria.—Dr. E. Tietze "On the Eocene Formation south of Glina, in Croatia." It consists of three members; the lowest a fresh-water deposit, with Planorbis, and traces of coal; the middle, green sandstones alternating with marly beds, probably identical with the so-called Albarese or Galesstro of the Appennine mountains; and the upper, formed of slaty sandstones with fucoids.

THURSDAY, JANUARY 4, 1872

BRITISH PREPARATIONS FOR THE APPROACHING TRANSIT OF VENUS

IN nearly all those countries of Europe in which Astronomy is nationally cultivated, preparations are being made for thorough observation of the first of the coming Transits of Venus, which will occur on December 8, 1874. In Russia, whose territory presents many favourable points for observation of the phenomenon, a committee, organised by Professor Struve, has had under consideration during the past two years the establishment of a chain of observers at positions 100 miles apart along the region comprised between Kamschatka and the Black Sea. The principal astronomers of Germany have held two conferences, each of several days' duration, which have resulted in a decision to furnish four stations for heliometric observation of the planet during its transit: one of these will be in Japan or China, and the others probably at Mauritius, Kerguelen's and Auckland Islands; and three of these, with the addition of a fourth station in Persia, between Mascate and Teheran, will be equipped for photographic observations also. A French commission on the subject sat before the war, and reported to the Bureau des Longitudes that it was desirable for their government to provide for observing stations at Saint Paul's Islands, and Amsterdam, Yokohama, Tahiti, Noumea, Mascate, and Suez. Since the close of the war the subject has been reverted to, and lately the Academy of Sciences applied to the Government for the requisite funds; but these could not be granted till next year, the budget for 1872 having been disposed of.

The British preparations, to which we shall chiefly confine our remarks, are, we believe, in a more advanced state than those of any other country. This forwardness may probably be ascribed to the circumstance that they have from the first been directed by a single mind, and have thus been freed from the inevitable delays of a committee. The Astronomer Royal first called attention to the Transits in 1857 and again in 1864. In 1868 he commenced to shape definite plans, selected the observing stations which were in all respects most suitable for British occupation, and opened communications with the Government upon the financial requirements of the undertaking.

Presuming a general acquaintance with the phenomenon under notice, and its availability for determination of the parallax of Venus, and that of the Sun (a subject that has been well popularised), we merely remark that there are several methods by which observers at opposite points on the earth may measure the parallactic displacement of Venus upon the Sun's disc: (1) by durations of Transit (Halley's method); (2) by absolute local times of ingress and egress (Delisle's method); (3) by heliometric measures of the planet referred to the limbs of the sun; (4) by similar measures obtained from photographs of the sun with the planet on his disc. The first of these has been considered disadvantageous for the 1874 Transit, which is the one that immediately concerns us. The third and fourth are of recent suggestion, and have

been regarded as of doubtful accuracy, especially the fourth, whose reliability is still the subject of experimental inquiry. The second was the one which demanded foremost attention. The Astronomer Royal, therefore, as a first step, set down the stations best available for its application. These had to be selected in order to combine a sufficient altitude of the sun with the maximum attainable acceleration of ingress and retardation of egress on one side of the earth, and retardation of ingress and acceleration of egress on the other side of the earth. And after weeding the lists for each phase of such stations as were expected to be provided for by foreign governments, and of those already occupied by established colonial observatories, it was found that there were five stations which it was desirable that England should prepare to equip. These were Woahoo (for observation of accelerated ingress), Kerguelen's and Rodriguez Islands (for the retarded ingress), Auckland in New Zealand (for the accelerated egress), and Alexandria (for the retarded egress).

Now, as at all these places the absolute local time of the phenomenon is required, it is indispensable that the longitude of each be very exactly known. In no one case does a sufficiently accurate determination of this element exist, and provision must therefore be made in each case for obtaining it. This vastly increases the extent of preparations for the instrumental equipment of the stations, and renders necessary a three or four months' sojourn of the observers at each. Of the methods for determining longitude which were open to choice, the Astronomer Royal decided to employ that by vertical transits of the moon, and for observing these he resolved upon supplying altitude instruments with fourteen-inch circles and telescopes of twenty inches focus. For time determinations he proposed three-inch transits, of thirty-six inches focus, with clocks of moderately high class. For observing the phenomenon he elected to employ at each station one six-inch equatorial and one four-inch portable telescope. For these an observatory of three rooms was required. With the exception of one altazimuth, two clocks, and two or three four-inch telescopes, which the Greenwich Observatory could furnish, all the specified instruments and the observing rooms had to be specially provided. An estimate for their purchase and construction, amounting to 2,154*l.*, was therefore submitted to the Admiralty. Some needful chronometers and meteorological instruments were available from home stores. To the above estimate for material requirements were added others, prepared by Admiral Richards, for the personal expenses, the conveyance, residence, pay, and contingencies, of the observing parties. These amounted, for the Woahoo detachment, to 2,500*l.*, for the Rodriguez and Kerguelen's parties to 2,000*l.* each, for the Auckland party to 1,000*l.*, and for Alexandria to 750*l.*, making a total of 8,250*l.* The grand total of 10,500*l.* was asked of the Treasury in May 1869, and immediately granted.

The construction of the requisite instruments and clocks was forthwith commenced, by Messrs. Troughton and Simms and Messrs. Dent. Three six-inch equatorials happening, however, at the time to come into the market, they were at once purchased; one of the three being that which is known to fame as the "Lee Equatorial," and is the instrument used by Admiral Smyth in the preparation of his "Celestial Cycle." The observatories were put in

hand also. They are somewhat substantial structures, formed of a stout wooden framework, covered with weather-boarding and roofed with zinc and roofing-felt. Each instrument has a separate hut. The transit huts are ten feet square, with walls six feet high, and with the shutter openings a little on one side of the centre, so as to leave good room for mounting the clock, &c. The altazimuth huts are planned on a nine-feet hexagon. Their domes are hexagonal pyramids erected on circular frames, which are grooved to run on six-inch rollers. These rollers, six for each dome, are mounted on the wall-curbs. One flap-back shutter gives sky view from the horizon to the zenith. Each hut is made portable by being constructed in sections which are connected together by bolts and nuts. For the transit instruments massive Portland stone piers and foundation slabs have been provided; for the altazimuths stone pier-caps only will be sent out, leaving the piers to be provided on the spot. Every part of each observatory and every packing case has been numbered and marked by stencilling, with a letter to denote the station for which it is destined.

These transit and altazimuth observatories, with their instruments and the primary clocks, are, with trifling exceptions, in perfect readiness for use. The equatorials are generally ready, though their final completion has been interrupted by the loan of portions of them to the observers of the recent solar eclipse. The telescopes will be supplied with the Astronomer Royal's prismatic eye-piece for correction of atmospheric dispersion, which will necessarily be considerable at the low altitudes at which some of the contact observations must be made. The equatorial observatories are not yet constructed; the plans for them are under consideration as we write. The four-inch telescopes, some second-class clocks for use with the altazimuths and equatorials, and the small accessories, have also to be provided.

It is early to speak of the *personnel* of the various observing expeditions. Officers of the army and navy will probably compose a large proportion of the observing corps. Several gentlemen of the Royal Artillery have already commenced practice at Greenwich with the time and position instruments; but, with the object of forming a more accessible school of observation for them, a temporary observatory has been fitted up near to their headquarters at Woolwich.

Photography was not included in the Astronomer Royal's original plans. But from the time that his preparations were first mooted, the probable advantages of photo-heliometry of the planet during transit were strongly insisted upon. The plans for photography were advanced from photographic quarters; astronomers of the exact class who were not photographers were somewhat sceptical at the outset concerning its accuracy. They anticipated that uncertainties would attach to the photographic measurements: in the first place from optical distortion of the image formed by the camera-telescope; in the second place, from mechanical distortion produced by unequal shrinkage of the collodion film, which must receive its impression in the wet state, whereas the measurements must be taken when it is dry; and in the third place, it appeared doubtful whether sufficiently accurate scale measurements could be secured to make the results equally reliable with those to be obtained from eye obser-

vation of the contacts. No method of secondary accuracy could be tolerated, since the received value of the solar parallax ($8''\cdot95$) is probably much less than 1 per cent. in error. It is considered that an eye-observation of contact, *i.e.* of formation or rupture of the "black drop," can well be made with no greater error than 4 seconds of time. As Venus moves over the sun at the rate of about $2''$ in a minute of time, the 4 seconds correspond to a displacement of $0''\cdot12$ of arc in the direction of motion, or about $\frac{1}{1000}$ of the sun's diameter. Can the measurements from a photograph, with all the above noted chances of error, be relied upon for such small quantities? It is argued that they can. The probable error of a single micrometric measurement of the photographic distance of the images of a double star is cited by Mr. Asaph Hall* to be $0''\cdot12$, and Mr. De La Rue, who is naturally the English referee in such matters, has no hesitation in saying that the measurements from a solar photograph *may* be depended upon, with all due precautions, to the $\frac{1}{1000}$ of the sun's diameter. He is of opinion that the shrinkage of the collodion film takes place only in the direction of its thickness, and he considers that if any optical distortion exists, it may be determined, and the correction for it found, by photographing a scale of equal divisions upon different parts of a plate, and comparing micrometric measurements of the various images. Upon this point he is about to make some crucial experiments with a large scale erected upon the Pagoda at Kew, and photographed from the Kew Observatory with the image in all positions on the sensitive plate. Herr Paschen is also investigating the matter on the part of the German Commission, using for his test-scale a glass plate divided into squares by diamond-ruled lines. Some preliminary trials have convinced him that should it be impossible to get rid of distortion, it will yet be easy to correct for it as accurately as may be desired.

Although the thorough reliability of the photographic method has not yet been satisfactorily established, the doubts concerning it have been in part removed, and it has appeared undesirable to neglect photography in the face of the circumstance that it might be the means of obtaining some useful record of the transit at stations where from atmospheric causes the observations of contact may be lost or vitiated. Moreover, as other nations had decided to employ the photographic method, it seemed incumbent upon Britain to work in harmony if not in actual concert with them; for although there has as yet been no formal proposal for international co-operation, there have been communications between the astronomical authorities of the various countries concerned, which have prevented the formation of very divergent plans. The Astronomer Royal therefore laid the subject before the Board of Visitors of the Greenwich Observatory, at their meeting in June last, and it was fully discussed by them. They resolved that it was desirable to furnish all the English stations chosen for eye observations with the necessary photographic appliances, and an application was shortly afterwards addressed to the Treasury for a grant of 5,000*l.* to defray the expenses of the additional equipment. The money was granted, and the construction of the photo-heliographs—five in number—was forthwith placed in Mr. Dallmeyer's hands. These instruments will be of generally

* *Silliman's Journal*, vol. cii., p. 26.

similar design to one made by the same artist for the Wilna Observatory, which has produced sun-pictures that, so far as the eye can judge, leave nothing to be desired in point of sharpness of definition and freedom from such distortion as the photographed cross-wires can exhibit. The object-glasses will be of about 4in. diameter, giving focal images of the sun about half an inch in diameter. The focal image will be amplified to about 4in diameter on the photographic plate, and, in applying the enlarging lens, Mr. Dallmeyer is confident that he can entirely destroy the spherical aberration. The camera-telescopes will be mounted on equatorial stands, with latitude adjustment of 80° range; and they will be furnished with driving clocks.*

For the general photographic organisation, the Astronomer Royal has secured the co-operation of Mr. De La Rue, under whose able supervision the instruments above mentioned will be constructed, and by whom the various details of the photographic scheme will doubtless be arranged. Of the five stations already selected for eye observation of contacts, three are well suited for photographic record. These are Rodriguez, Kerguelen's, and Auckland, at all of which the whole transit will be visible. The Hawaiian station and Alexandria, though they are available, are less advantageous than the rest, because only a portion (about half) of the transit will be visible from each, and the photographs, besides being thus limited, must be obtained at low altitudes of the sun. It may become a question whether the heliographs provided with a view to furnishing these two stations cannot be more advantageously located. But before the positions are finally decided upon, it appears desirable that the intentions of other nations should be fully known, or, as would be preferable, that the ultimate distribution of observers of all kinds—telescopic, heliometric, and photographic—should be made the subject of an International Conference.

J. CARPENTER

JUKES'S MANUAL OF GEOLOGY

The Student's Manual of Geology. By J. Beete Jukes F.R.S. Third edition, re-cast, and in great part re-written. Edited by Archibald Geikie, F.R.S. (Edinburgh: A. and C. Black, 1872.)

IF there be any one feature more strongly marked in the present age than another indicative of progress and intellectual advancement, it is the superiority of most (we will not say of all) of the books intended to promote education. School books and class books of all kinds, instead of being merely reprints, as in the days of yore, now really undergo revision every five years or so, or are superseded by new ones; whilst the introduction of natural science teaching into our Universities and public schools has created a demand for text-books to an extent greater even than the supply.

Among the various writers of the day on the science of Geology, Sir Charles Lyell must undoubtedly be placed in the front rank, as having done more than any other man

to promote its study, and his "Principles" and "Elements" of Geology still hold the highest places in our estimation; but we must not forget that Phillips, Dana, and Jukes have also furnished us with geological manuals, more elementary in their style and arrangement, and therefore more serviceable for beginners than are Lyell's works. In order, however, to remedy this, Sir Charles Lyell has lately brought out a "Student's Elements of Geology," 8vo. pp. 624 (Murray), being an abridged edition of his larger work. This will no doubt prove a very useful book to beginners as an introduction to the higher class books.

Jukes's "Student's Manual of Geology" was born in 1857, and has already gone through two previous editions, each time, as is the sad fate of such books, growing more corpulent, till the poor student turns pale before the vast array of facts, neatly arranged for him to "cram," in the smallest possible type.

The original design contemplated in 1854 was an article on Geology for the "Encyclopædia Britannica," to have been carried out by the late Prof. Edward Forbes and Mr. J. Beete Jukes conjointly; but the death of Forbes for a time deferred the task. It was afterwards inserted in the Encyclopædia under "M," as "Mineralogical Science," and finally appeared as a separate work in 1857. The first edition is comprised in 610 pp., and is illustrated by 74 woodcuts, chiefly diagrams and sections of rocks, &c.

The second edition appeared in 1862, having grown an inch in the size of its page, and added 154 pages to its bulk, partly owing to the addition of 100 more illustrations, 50 of which are of fossils, or rather groups of fossils.

The idea of these figures of "Fossil groups," as they are termed, seems to have been taken from the admirable series of little woodcuts which illustrate the invertebrate portion of Owen's "Palæontology,"* prepared by the late Dr. S. P. Woodward. They are, however, arranged stratigraphically in Jukes's "Manual," not zoologically, as in Owen's "Palæontology."

The third edition, now before us, is only fourteen pages thicker than the second edition, and contains thirty-one more illustrations; but the bulk of matter is vastly increased by the use of smaller type than in the former editions.

The illness which seized Mr. Jukes, and by which he was removed from among us, had already impaired his health so much as to render it desirable he should be relieved of the labour of completing this edition, and the task was accordingly, by the author's own wish, undertaken by Professor Geikie, Director of the Geological Survey of Scotland.

The eighty pages on mineralogy (forming chapters II. and III.) have been entirely re-written by Dr. Sullivan; Chapter XIII., on trap-rocks, has been re-written by Prof. Geikie, as well as many other parts. Mr. Hull has revised the description of the English Coal-measures. Messrs. Bristow, Whitaker, and Judd have looked over the Mesozoic and Cainozoic chapters, and Prof. Huxley has contributed a new synopsis of the animal kingdom.

By a modification of the former edition, a new part is introduced (Part II.) called "Geological Agencies, or Dynamical Geology," a part of which also is from the pen

* There are grounds for hoping that the same artist will construct some precisely similar photo-heliographs for other countries, for use on the Venus Transit. There would manifestly be great advantage in the employment by all photographing observers of instruments whose optical portions at least are of identical material and manufacture.

* Second Edition, 1861 (Edinburgh: A. and C. Black).

of Prof. Geikie, and now appears for the first time. It treats of the origin of hills, lakes, valleys, caverns, passes, fjords, glaciers, river-deposits, sea-action, coral-reefs, and all the many phenomena which either are themselves the cause, or the effect, of geological agents.

We have such a strong feeling against making a reference-book, especially one intended for the use of students, too bulky to be conveniently handled, and even carried about with one, as is frequently needful, that we have looked most closely into the present edition to see in what way it may be reduced without injury, bearing in mind that it only purports to be "a Student's Manual of Geology."

Candidly, then (without the least disrespect to Dr. Sullivan), we think the two chapters on chemistry and mineralogy (chapters II. and III., occupying eighty-one pages) should have been omitted. For these sciences, although so intimately related to, and constantly extending their aid to geology, are equals in rank and importance as sciences, and the student, if intending properly to master them, must possess such text-books as Williamson's Student's Chemistry and Dana's System of Mineralogy, books of equal importance in these sciences to Lyell's or Jukes's geological works.

As might naturally be expected in a text-book framed by a Geological Surveyor deeply versed in all the intricacies of rock structures in the field, and constantly dealing with stratigraphical questions, the book treats most largely of physical geology, not, however, to the exclusion of paleontology; yet exalting petrological science—at present in its infancy—into a far higher place than it has hitherto occupied in any other similar work. We do not wish it to be understood that we desire to undervalue lithological characters, especially in rocks devoid of organic remains; but we find such conflicting opinions prevalent among petrologists, that we are led to doubt the possibility of teaching much of such a branch of geological science to the student until the nomenclature of the principal rocks is settled by a congress of geologists, mineralogists, and chemists, or by some other authoritative body.

If in a new edition the mineralogy is omitted, we would suggest the introduction of a glossary of geological and zoological terms, which the beginner would, we feel sure, be very grateful to find added to the index, as an addition to the valuable tables of classification contributed by Prof. Huxley.

We heartily recommend the book to both intending teachers and students, who will find it a most complete compendium of geological science, and still one of the best Manuals in our language, as it has now been brought by its editor, Prof. Geikie, fairly "abreast of the onward march of science."

BREHM'S BIRD-LIFE

Bird-Life. By Dr. A. E. Brehm. Translated from the German by H. M. Labouchere, F.Z.S., and W. Jesse, C.M.Z.S. Parts I.—III. (London: Van Voorst, 1871.)

MR. WILLIAM JESSE, at the instigation of his colleague, is doing his best to make a silk purse out of—well, we do not wish to be rude, so let us say,

out of materials of which silk purses are not commonly made; for Dr. Alfred Edmund Brehm has the fatal facility of being able to write endless nonsense on a subject which, in better hands, might be made truly instructive. He is so far from being a true naturalist that he is constantly being misled, confounding analogies with homologies. Take his second paragraph, as Mr. Jesse translates it, and translates it very well too:—

"Birds have much in common with mammals; and it is certain that some striking resemblances between individuals of both classes cannot be denied. Every impartial observer must recognise in the eagle the image of the lion, or rather its true representative in the bird-world; in the owl we see the cat; the raven resembles the dog; the vulture, the hyæna; the hawk, the fox; the parrot, the monkey; the cross-bill, the squirrel; the wren, the mouse; the butcher-bird, the weasel; the bustard, the stag or antelope; the ostrich, the camel; the cassowary, the llama; the dipper, the water-rat; the duck, the duck-billed platypus; the diver, the otter; the auk, the seal; and so on. In spite of all these resemblances, which, after all, only apply to the external aspect, the bird is always and essentially distinct from mammals" (p. 2).

What, then, is the use of all this? Even the translator has to append a note stating that the author has not truly explained what he is writing about, and, indeed, it is plain that the writer to whom such ideas as the foregoing occurred has no pretension to be accounted a scientific man. Their association jars upon the feelings and contravenes the knowledge of any student of morphology. We have no wish to shock our readers even with the commonest terms of German philosophy, but is it not clear that to draw a parallel between a raven and a dog, and between a butcher-bird and a weasel, while a fox is likened to a hawk and a water-rat to a dipper, is simply a *subjective* process, depending entirely on the fancy of the beholder? Of what use then are any speculations on "Bird Life" by such an one? To most men the observation of the aspects of nature, as exhibited under divers conditions of country and climate, afford a most instructive education. To Dr. A. E. Brehm it seems to be otherwise. He has wandered in many lands, and has seen in their homes the faunas of both north and south. The only effect this seems to have had upon him is to teach him that he lives. "Movement is life" we read (p. 19), "and life is the power of self-motion." Motion is therefore the chief characteristic of birds. "The bird is, of all creatures, the most versatile in its movements; it runs, climbs, swims, dives, and flies" (p. 20). He is careful to add that all these qualities are not to be found in a single species; but may not just as much be said for the insect or the mammal; or even if the dreams of some geologists be well-founded, might they not all have been found "combined in one creature"? A contemporary of the pterodactyls might, with some appearance of truth, have applied to one of them the description of Milton's fiend, who

O'er bog, or steep, through h strait, rough, dense, or rare,
With hand, head, wings, or feet, pursues his way,
And swims, or sinks, or wades, or creeps, or flies.

So far as powers of locomotion go, and by "movement" Dr. Brehm plainly means locomotion, the bird is hardly superior to the insect or the mammal. But to return to the extraordinary hypothesis that "movement is life," and the converse. The most miserable savage that ever

plucked a mussel from the rock knows better in this respect than Dr. Brehm; and when the latter tells us, *à propos* of the songs of birds (p. 37), that the "voice is still motion," and we connect the statement with a previous assertion (p. 19), that "worlds roll on through boundless space—and live," we feel certain that we ought to hear the music of the spheres, or some other mystical sweet sounds, if we could only elevate ourselves to his exalted ecstasy.

But we think we need not trespass further on the time of our readers. We will conclude by expressing the hope that when Mr. Jesse and Mr. Labouchere next set about translating a German author they will have better luck in pitching upon a subject—and they will easily find one—for their labours than the rhapsodies of Dr. Alfred Edmund Brehm.

OUR BOOK SHELF

Proceedings of the London Mathematical Society. Vol. iii., Nos. 21–40.

THE papers read before this Society still preserve the high character attributed to them in the notice of vol. ii., which appeared in this journal. That such should be the case is not matter for surprise, when we run our eyes over the list of contributors. The principal authors are Prof. Cayley and Mr. Samuel Roberts. The former furnishes three memoirs on quartic surfaces (pp. 59–69; 198–202; 234–266); sketch of recent researches upon quartic and quintic surfaces; rational transformation between two spaces (pp. 127–180); on Plücker's models of certain quartic surfaces. The latter communicates papers on the order of the discriminants of a ternary form; pedals of conic sections (pp. 88–98); on the ovals of Des Cartes (pp. 105–126); on the order and singularities of the parallel of an algebraical curve (pp. 209–259); on the motion of a plane under certain conditions. Prof. Clerk Maxwell contributes a paper on the mathematical classification of physical quantities. Besides the foregoing communications, the above-named gentlemen have laid other papers before the Society. Memoirs have also been presented by Mr. J. Griffiths, Mr. J. J. Walker, Prof. Clifford, Hon. J. W. Strutt, and other members. Some other highly valuable communications, we learn from the "Proceedings," were made to the Society, but no record has as yet been made of them, their authors not having yet sent their completed papers for publication. The Society, from the number and high character of its memoirs, seems to have met a want, and is, perhaps, the only Society before which many of the communications could have been brought. As generally the papers are worked out in some detail at the meetings, members have an interesting opportunity of seeing how some of our foremost mathematicians employ their divers instruments. The Society has lost by death during the past session, its first president, and one of its earliest warm supporters. A slight sketch of Prof. De Morgan and his works appeared in NATURE close upon his death in March last. The eighth session of the Society's existence has just commenced, and we trust its future work may be as good as that it has already achieved. *Floreat.*

Treatise on Terrestrial Magnetism. (Blackwood and Sons.)

THE first half of this book contains a good deal of information, and some inquiries connected with the question of the secular variations in the magnetic elements. The author, on the supposition that the secular changes in the declination are caused by the action of a single, slowly rotating pole on a needle which at each place is locally influenced in a definite and determinable manner, com-

putes the declination at several places, and shows that it agrees tolerably well with actual observation. The rotating pole he places at a constant distance of $23^{\circ} 30'$ from the pole of the earth's axis, and gives to its rotation a period of 640 years. The latter part of the book, however, is taken up with "an hypothesis." The writer of this book, and many other such writers, would do well to remember the words of Newton, "*Hypotheses non fingo*." The hypothesis referred to is simply this:—that the sun attracts the electric matter in the earth and carries it round in a sort of tidal wave, this causes an electric current from east to west, which causes the magnet to point to the north, and from which the writer also attempts to deduce some of the other phenomena of magnetism. There seems to us to be some ambiguity in the writer's method of expression, so that we do not clearly gather whether he intends this current to account for the whole magnetic action of the world, or only for the variations of it. A consideration of the character of the variations of the needle is sufficient to overthrow the hypothesis announced by our author. The solar diurnal variation is thus explained by him:—The pole of the ecliptic revolves once a day round the pole of the earth's axis, the needle tends to follow this, and hence the solar diurnal variation. Now, we may point out a circumstance which, apparently, entirely overthrows, not only this hypothesis, but any which attempts to account for that variation by anything of the nature of the movement of a magnetic pole. At Point Barrow the needle points N.E., at Port Kennedy it points S.W., yet at each place the solar diurnal variation follows local time and exhibits precisely the same features. Standing, then, at the centre of the needle, and looking towards its marked end, that end would at both places be observed to be moving towards the left hand of the observer between the hours of 8 A.M. and 1 P.M. But since the needles are pointing in opposite directions, this constitutes a movement of the marked end of the one towards the geographical west, and of the marked end of the other towards the geographical east, and this at times when the needles are under precisely the same circumstances with respect to the sun's influence. Now, no movement of the magnetic pole can account for this, it would necessarily entail a movement of the marked end of both these needles in the same geographical direction. The consideration of this phenomenon shows us that if the solar diurnal variation of the declination is to be attributed to a current, it must be one not round the magnetic pole or the geographical pole, but along the magnetic meridian. But this is not the place for us to discuss this question further at present. It would seem to be, however, rather from the consideration of such phenomena as this in a careful and accurate way, and the attempt therefrom, by induction, to arrive at laws, that we may hope to form a theory of terrestrial magnetism, than from "making an hypothesis," and then attempting to apply it to facts.

J. S.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Mayer and De Saussure

IN Prof. Tyndall's account of the labours of Mayer, a paragraph is devoted to the bearing of his principles upon the phenomena of vegetable life. It suggests two points of difficulty to me:—

1. It is said that "Mayer's utterances are far from being anticipated by vague statements regarding the 'stimulus' of light, or regarding coal as 'bottled sunlight.'" Nevertheless the paragraph reads almost like a paraphrase of the following passage from Sir John Herschel's "Outlines of Astronomy" (1833), p. 211:—

"The sun's rays are the ultimate source of almost every motion which takes place upon the surface of the earth. By its heat are produced all winds and those disturbances in the electric equilibrium of the atmosphere, which give rise to the phenomena of terrestrial magnetism. By their vivifying action vegetables are elaborated from inorganic matter, and become in their turn the support of animals and men, and the sources of those great deposits of dynamical efficiency which are laid up for human use in our coal strata. By them the waters of the sea are made to circulate in vapour through the air and irrigate the land, producing springs and rivers. By them are produced all disturbances of the chemical equilibrium of Nature, which by a series of compositions and decompositions give rise to new products and originate a transfer of materials."

In a note in Mr. Herbert Spencer's "First Principles" (2nd Ed., p. 496), which first led me to look at this passage, it is remarked that Herschel "expressly includes all geologic, meteorologic, and vital actions, as also those which we produce by the combustion of coal," in the effects of the solar rays. When, therefore, Prof. Tyndall states that Mayer *revealed* the source of the energies of the vegetable world, it appears to me that Herschel anticipated the revelation twelve years previously. Of course I apprehend that Mayer's merit consisted in seizing at once a physical principle of immense generality, and in applying it to very different phenomena. Herschel began at the other end; but appears equally to have seen the solar energy underlying these phenomena, though in a general way, and without demonstrating numerical relations.

De Saussure is credited unreservedly with the observation of the reducing power of the solar rays in the vegetable economy. But he seems to me, as, indeed, he seemed to himself, to have only crowned a theory which other workers had elaborated. Priestley began by ascertaining that air depurated by animals was purified by plants. Ingenhousz showed, what Priestley candidly confesses he missed, that this effect is due "chiefly, if not only, to the light" of the sun. Senebier found that "fixed air" was the ingredient which plants removed from a vitiated atmosphere, and that this underwent elaboration in the tissues, oxygen being set free as the result.* Lavoisier having previously shown that fixed air was a compound of carbon and oxygen, Senebier's results implied the fixation of carbon by plants. This fixation De Saussure actually demonstrated by feeding a plant with carbon dioxide and water alone, and showing that the carbon in the tissues increased. He further found the unexpected fact (and this is what he added to the matter) that the oxygen evolved by plants does not correspond to that contained in the carbon dioxide absorbed, but that it is smaller in quantity.

De Saussure's researches are a beautiful example of quantitative work, but they would have, I imagine, merit of a different order if Priestley, Ingenhousz, Senebier, and Lavoisier had not broken ground before them.

W. T. THISELTON DYER

Phenomena of Contact

IN NATURE of August 24 I objected to, as misleading, the statement by Mr. Newcomb that "we find ligaments, black drops, and distortions sometimes seen in interior contacts of the limbs of Mercury or Venus with that of the sun, described as if they were regular phenomena of a transit, without any mention of the facts and experiments which indicated that these phenomena are simple products of insufficient optical power and bad definition which disappear in a fair atmosphere with a good telescope well adjusted to focus." I asked for references to the facts and experiments by which the statements are justified.

IN NATURE of September 28 I find Mr. Newcomb's reply, but without the references which I desired. Mr. Newcomb considers that I controvert the two following propositions:—

1. That the irregular phenomena of internal contact of a planet with the sun, variously described as distortions, black drops, ligaments, &c., are not always present, but are only seen sometimes.

2. That when seen they are due to insufficient optical power or bad definition.

If the word "irregular" is cut out, and the word "seen" substituted for "present" in proposition (1) there can be no doubt about its truth. It will be found that all the arguments adduced

by Mr. Newcomb to prove this proposition have no bearing either upon the word "irregular" or "present" in contradistinction to "seen."

It appears to me, therefore, quite unnecessary to allude further to this proposition.

With reference to proposition (2), I believe it to be utterly erroneous. I believe that the phenomena of the fine connecting ligament can only be seen in a fair atmosphere, with a good telescope well adjusted to focus, and with considerable magnifying power. When it is remembered that the fine connecting ligament is confined to within about a second of arc of the sun's limb, I think my statement will at least commend itself to practical observers. Mr. Newcomb appears to regard it as a great difficulty in my view of these phenomena, that some of the observers should see the ligament and some not. I am rather surprised at the persistence with which this point is again and again brought forward in his letter. I thought that it had been answered by anticipation in my letter which appeared in your number of August 24. In all my writings upon the subject I have maintained that the phenomena could only be seen under favourable circumstances and with sufficient power; and in my letter of August 24 will be found this statement, which appears to have been entirely overlooked, at least unanswered, by Mr. Newcomb:—"The optical enlargement by irradiation is a function of the brightness, and can be made insensible by sufficiently diminishing that brightness. Unfortunately, however, when this diminution of brightness is carried to a very great extent, errors in an exactly opposite direction to those of irradiation will come into play, similar, in fact, to the results of Wolf's experiments. The observations of Mercury on the sun's disc in 1863 were made with very different optical means, and some very different methods were adopted for diminishing the sun's glare." In my view those observers who did not see the connecting ligaments failed to see it, either from want of attention to the point as not a contact such as they expected to see, or from the observations having been made under such circumstances that some of the necessary conditions which I have indicated were not satisfied.

The fine connecting ligament is only seen by contrast against the illumination of the sun's disc near the point of contact, and it may well be that some of the observers have pushed the diminution of brightness of the sun's image to such an extent that the contrast was too feeble to attract attention before the apparent contact. To me, and I think to others who will give the matter some consideration, it is clear enough "that an observer with the naked eye, a telescope of low power, would not, in the case of a transit of Venus, see the connecting ligament at all." It is as clear "that without seeing any ligament, the planet, at egress, would appear to touch the limb without distortion, necessarily, earlier than the contact would appear to be established to observers who were watching the transit with good telescopes and with high powers." It appears to me equally clear that, if the brightness of the sun's image be reduced to excess, then the ever-diminishing small portion of the illuminated disc between the sun's edge and the advancing planet, at egress, may be made to disappear, from sheer inability to appreciate so faint a light, before the contact would appear to be established to observers who had not so reduced the brightness of the image. Disturbing causes such as these do exist, and their effects must be recognised. I must apologise for bringing forward such arguments; but, since one observer has published his opinion that the "ligaments, &c." do not exist in contacts, because he looked at the transit of Mercury with an opera glass and saw nothing of the kind, it would appear necessary to recall attention to a common-sense view of the points at issue.

But whatever may be the opinion of Mr. Newcomb respecting the explanation which I have given of the probable reason why some of the observers have not seen the connecting ligament, he must feel that it will at least be difficult for him to explain away the positive evidence of the numerous observers who profess to have seen the ligament with first-rate telescopes. Some of them, at least, were gentlemen not likely to have forgotten to adjust their eye-pieces to focus, even if such a neglect would have produced the phenomena observed. In cases where the ligament has been seen, it will be found that the earlier lines of contact at egress have been given by observers with the best telescopes and high powers. This is strikingly shown by the Greenwich observations of the transit of Mercury, 1868. It is a result in perfect accord with my views. Very large and systematic discordances will be found to exist between the times of internal contact at the transit of Mercury, 1868, in cases where no connecting ligament was seen at all. This has been passed over in

* Recherches sur l'influence de la lumière solaire pour métamorphoser l'air fixe en air pur par la végétation, 1783.

silence by Mr. Newcomb; but it is important. It would be difficult to select from such groups of observers—the French, for example, who saw no connecting ligament—those who saw “the phenomena exactly as we know they are;” and unless this can be done, I am afraid that Mr. Newcomb’s somewhat unique argument upon this point might be made as easily to prove the converse as the result he deduces from it. All these observations, in my view, are good; but they are not strictly observations of the same phenomena.

Mr. Newcomb rejects at once the force of the evidence of the observers of the transits of Venus, 1761 and 1769, upon the question of the connecting ligament “till we have better evidence than now exists that their object-glasses were such as Clarke or Foucault would call good.” The phenomena connected with the ligament must be far more marked in the case of Venus than in that of Mercury, on account of the large diameter of Venus. To reject therefore by an impossible condition all the evidence in our possession respecting transits of Venus is certainly a bold step; but Mr. Newcomb appears to me to attach far too much importance, so far as irradiation phenomena are concerned, to the improvements effected in modern telescopes. The image of a point of light on the most perfect object-glass which can be conceived is not a point, but a disc, of which the illumination degrades rapidly from the centre, and which is surrounded by concentric rings of light. The law of degradation of the illumination of the central disc has been given by me in the Monthly Notices, November 1865. The result of theory upon these points has been most completely tested by experiment. The existence and regularity of these concentric circular rings is one of the most delicate tests of the perfection of a telescope. Since we have a disc of light corresponding to a point in the most perfect object-glass which can be made, the visible image of the sun formed by such a glass will not terminate with the geometrical image. This result of theory is confirmed by experiment. The optical enlargement found under degrees of illumination similar to those very commonly adopted in observations of the sun is amply sufficient to produce by its destruction near the point of contact the phenomena which so many observers of experience have declared that they have seen. That the optical enlargement is sufficient for the purpose can be seen from the experiments of Dr. Robinson, of Armagh, and from the Greenwich discussions of eclipse observations. This was pointed out in my letter in your number of August 24. With respect to Mr. Newcomb’s remark as to the application of this theory of irradiation to a transit of a planet, viz., “we require to know whether the irradiation of an extremely minute thread of light darkened so as to be barely visible is the same with that of a large disc, I am decidedly of opinion that it is not, and if not, the fact that the sun’s disc is optically enlarged by the telescope or the eye of the observer cannot be directly applied to the phenomena of transit.” I have merely to remark that Mr. Newcomb is undoubtedly right when he asserts that the irradiation from the minute thread of light darkened so as to be barely visible is not the same as that of the large disc. *It is simply because such is the case that the phenomena of the connecting ligament appear.* When the planet is well on the disc, the irradiation around the disc will not be disturbed, but as the planet approaches the edge, the irradiation near the point of contact must eventually be disturbed, and this disturbance, or change, gives rise to the phenomena observed—a black drop, connecting ligament, or whatever name you prefer to give to that apparent cutting out of a piece of the sun’s edge near the point of contact which must take place. After the disturbance of the irradiation has once commenced, the connecting ligament must at once increase in breadth; but I do not profess to be able to give the law of the changing form with any degree of exactness.

The experiments of Wolf and André were, as I stated in my letter of August 24, made upon a disc presenting no sensible traces of optical enlargement. The results can therefore have no bearing upon the question of irradiation. These results are undoubtedly valuable in themselves, as showing experimentally the tendency of errors of observations of contacts under feeble illumination. They may throw light upon those observations at which no connecting ligament was seen, but they are useless to disprove or prove irradiation effects.

My authority for stating that the observations of Wolf and André were made upon a disc showing no sensible traces of optical enlargement, is contained in the memoir itself. If Mr. Newcomb is pleased to call the phenomena of “telescopic irradiation” a species of bad definition, there can be no objection on my part

to his doing so; but it is not a species of bad definition “which disappears in a fair atmosphere, with a good telescope well adjusted to focus.”

With respect to the ligament not being a celestial reality. The contact is not a celestial reality. My views of the reality of the phenomena are that the reality is neither more nor less than the reality of the phenomena presented at the focus of an object-glass when turned upon a star. The irradiation can in my view be got rid of to the same extent and in the same manner that the central disc corresponding to the star’s image can be got rid of. You can reduce its dimensions by cutting down the illumination, and the disc will become a point, but only as it vanishes.

If I may be allowed to give one word of warning respecting the preparations for the transit of Venus 1874, it is *uniformity*. Make such arrangements as you think best, but once made stick to them even if not absolutely the best. The observations which are to be compared must be made as early as possible under the same optical conditions. The whole success or failure of the work will, in my opinion, turn upon the extent to which this necessary condition is approximated to.

E. J. STONE

Royal Observatory, Cape of Good Hope, Nov. 18, 1871

The Origin of Insects

WITH your kind permission I will answer Dr. Beale’s questions, published in his letter in your issue of December 21, 1871.

Dr. Beale asks me what part of the nervous system of the maggot is present in the fly? My answer is that I have traced the changes of the one directly into the other; and that Weismann has done the same. There is no time in the pupa state when the nervous system is absent; but it is difficult to demonstrate this, as amongst so much molecular matter it is not easily found, and is very easily crushed and destroyed.

Again, Dr. Beale asks me if I have seen any vestige of the mouth organs of the imago in the larva? I reply that the mandibles and maxillæ exist in the egg twelve hours before the young maggot emerges, together with the fore and hind-head segments; that these have all disappeared when the egg hatches; but that the imaginal discs are already formed at that time. Now, I would ask if it bears the slightest aspect of probability that the larval head segments and mandibles, maxillæ, &c., are formed for nothing, and that the imaginal discs are new formations arising contemporaneously with the disappearance of the larval head segments? Dr. Weismann has shown unmistakably that the abdominal segments of the pupa skin are formed from the abdominal segments of the larval skin. Does it appear in the slightest degree probable that the thoracic and head segments have a totally dissimilar origin? I admit that I have not been able to see the imaginal discs in contact with the head segments of the embryo; but I have found the imaginal discs immediately after the egg is hatched, and they are then too much like the embryonic structures alluded to, to have had any other probable origin. The proboscis is formed from cells laid down within these discs; of that there is not the smallest doubt. Dr. Weismann makes the same assertion, and, although I did not know it to be so at the time I wrote my work on the fly, I acknowledge it is so now, and that in my description of the origin of the proboscis I was wrong. In the Lepidoptera, and in some beetles, imaginal discs may be seen to have their origin in the inner layer of the larval skin.

Again, Dr. Beale says:—“Does Mr. Lowne mean to say, for instance, that he or any one else can adduce any reliable observations to prove that the sexual organs are gradually developed, even from the time when the embryo is enclosed within the egg?” I answer, yes. My own observations confirm those of Weismann on this head, and Dr. Beale will find, on looking again at page 112 of my book on the blow-fly, that he has not correctly quoted my statement. I will also refer Dr. Beale to Dr. E. Bessel’s paper, “Studien über die Entwicklung der sexual-Drüsen bei den Lepidopteren,” in the “Zeitschrift für wissenschaftliche Zoologie,” vol. xvii. I believe future observers will find the sexual organs are always so formed, even as they are in the vertebrata. There is another paper, by Siebold I think, on the same subject in the above-quoted periodical.

Lastly, Dr. Beale asks me to explain what I mean by the sentence occurring at page 116 of my book:—“All the tissues of the larva undergo degeneration, and the imaginal tissues are redeveloped,” &c. I apprehend that the redevelopment of all the

tissues does not imply also the redevelopment of the insect. That the tissues are all so redeveloped is undoubted, but they are not all redeveloped at once. I have stated in my book again and again that certain organs are redeveloped in a particular manner, and was never under the impression that the whole was a case of alternate generation. I did not know the origin of the imaginal discs in those days.

With your permission I will add a few words in support of the assertion "that the pupa change is analogous to ordinary ecdysis, of which it is a modification." In ordinary ecdysis the muscles undergo degeneration at their points of attachment to the cast skin; in metamorphosis this change is far more marked. In ecdysis in Chloëon, for instance, Sir J. Lubbock (Linn. Soc. Trans., vol. xxiv.) has shown that the wings and thorax are gradually developed through nine successive sheddings of the skin. In the more remarkable metamorphosis of Lepidoptera they are developed in two ecdyses, these two being called metamorphosis. Prof. Owen believed, and the assertion is now widely known, that the larvæ of such insects as the Orthoptera, Neuroptera, &c., exist in the maggot form in the egg; but the observations of Mr. Newport on Meloe, and of Fritz Müller, of Weismann, and many others, go far to prove that this is not so—that the maggot form is intermediate, the half-developed embryo and the pupa or perfect insect, being most alike.

The subject is one of great interest, and therefore I trust you will excuse this long trespass on your pages.

99, Guilford Street

BENJAMIN T. LOWNE

In Re Fungi

YOUR sarcastic correspondent "F. L. S." is quite incompetent to reply to my former letter. I did not call in question the correctness of the determination of *Agaricus cartilagineus*, but merely drew attention to the absurdity of the statement that the said determination was made from a mere "mass of mycelium," and that such a statement should come from a journal specially devoted to Botany.

In the original report of the occurrence of *Agaricus cartilagineus* (*Journal of Botany*, vol. iii, p. 28) special reference is there made to the "many-headed pileus;" now some of these "pilei" (not the "mycelium," "F. L. S.") were forwarded to the Rev. M. J. Berkeley for examination, and from these materials he (and not the writer of these lines) made out the plant to be *A. cartilagineus*. Certainly I included the species "without hesitation" in the list of Middlesex Fungi, because I knew the plant referred to had not been determined from a mere "mass of mycelium," but that Mr. Berkeley had examined the perfected parts.

I fail to see why "F. L. S." is so anxious to "allay my alarm as to the decay of Fungology in England," especially as I have never expressed any "alarm" on that head. I do not look upon the *Journal* as such an infallible weathercock as to connect its wrong statement with a national breakdown in Botany; neither do I see how I have "missed the point" of its paragraph. I am more inclined to think that I have *hit it* in a friendly way, and rather hard too.

Mr. Baily on Kiltorkan Fossils

IN your last number Mr. Baily is said to have brought forward at a meeting of the Geological Society of Dublin "some strong facts to prove that the Irish palæontologists had not misled Prof. Heer, as stated by Mr. Carruthers at a recent meeting of the London Geological Society."

At the meeting referred to, Prof. Heer placed the Irish beds at the base of the Carboniferous series, mainly because *Sagenaria Veltheimiana*, a coal measure plant, was found in them.

Into this error I said "Prof. Heer had been led chiefly by the erroneous determination of the Kiltorkan *Lepidodendron* by the Irish palæontologists." I will not burden your columns with the strange history of the nomenclature of this plant, as I shall have an opportunity of doing this elsewhere ere long. The point before us is this, that Mr. Baily alone has the credit of erroneously determining the Kiltorkan plant to be the same as an already described Carboniferous species. And the proof of this is easily adduced. In 1864, Mr. Baily, in his "Explanation of Sheets 187, &c., of the Irish Survey," figures the fossil, and describes it unhesitatingly as "*Sagenaria Veltheimiana*, Sternb. sp." This he repeated in a paper by the lamented Prof. Jukes in 1866

(*Journal. Geol. Soc. Ireland*, i. pp. 123, 124), as well as in a paper by himself read to the Natural History Society of Dublin in the same year (p. 2). Prof. Heer acknowledged his obligations to Mr. Baily for the Irish specimens he had examined. I have examined specimens so distributed by Mr. Baily, and they were named *Sagenaria Veltheimiana*.

In the volume of the British Association Reports, published in 1869, Mr. Baily says (p. 59) that the *Sagenaria* is named by Schimper *S. Bailyana*. More recently (Nov. 1871), in his "Figures of British Fossils" (p. 84), he names it *Knorrria Bailyana*. It is not much to the purpose to say that it is neither a *Knorrria* nor a *Sagenaria*, or further that the specific designation *Bailyana* must give place, with some dozen other synonyms, to the original name given by Dr. Haughton in 1855. But it is to the purpose to notice that *Sagenaria Veltheimiana* is not a Kiltorkan fossil, though said to be so by Mr. Baily, and that this error, now acknowledged by Mr. Baily himself, was the main foundation of Prof. Heer's argument.

I am not a little curious to know what are the "strong facts" which will overthrow a plain narrative that fully justifies my statement, but at the same time compels me to make it more personal than the truth seemed to me to demand when I made it some months ago.

WILLIAM CARRUTHERS

ZOOLOGICAL RESULTS OF THE ECLIPSE EXPEDITION

A STEAMER is eminently unqualified for observations on marine zoology. Owing to the high rate of speed, it is impossible to use a towing net with any success, and to a zoologist it is perfectly tantalising to see swarms of Medusæ, &c., sail past the ship without being able to obtain a single specimen. In Peninsular and Oriental ships the only practicable method is to keep the tap of the baths constantly running through a fine gauze net. In this way quantities of Entomostraca may be obtained. Since we have been in the Red Sea, the water has been splendidly phosphorescent every night, the light being most brilliant where the hot water from the condensers is shed out into the sea, the animals being probably killed by the heat, and emitting in the act one last brilliant flash. If the water be turned on into one of the baths at night, most gorgeous flashes of light are obtained, and the animals causing them may be caught in small vessels and kept for examination. They are at present almost exclusively Entomostraca of the genera *Cypris*, *Cyclops*, and *Daphnia*. When the light is examined spectroscopically, it gives a spectrum in which only the green and yellow are present, the red and blue being sharply cut off. Several species of the Entomostraca obtained contain a brilliant red pigment, which gives unfortunately no absorption bands when examined with the micro-spectroscope. At Suez I obtained a number of Echinodermata of the usual dark purple tint, a splendid *Cematula* in abundance, two species of *Echinus*, and one or two star-fishes. The colouring matter of these animals is readily soluble in fresh water or alcohol, as is that of the common British feather-star. Though its colour is extremely intense, it gives no absorption bands, but when a strong solution is used, the spectrum is reduced to a red band, all the rest of the light being absorbed. Apparently parasitic on a large flat *Spatangus*, were obtained a number of red Planarians, about one-eighth inch long, which gave the characteristic absorption bands of hæmoglobin with great intensity. The existence of hæmoglobin in Planarians is a fact of considerable interest, and I believe quite new. On taking a boat excursion round the shores, where I obtained abundance of large Gasteropods and the Echinodermata mentioned above, I was remarkably struck by the absence of Actinias. Though I was out nearly the whole day, I did not see a single specimen, nor indeed did I observe any large Medusæ. This absence of these latter may perhaps, however, have been due to the set of the wind or tide.

Of the Suez Canal fauna we were able to observe very little, except that the canal perfectly swarms with fish from one end to the other. A good many were taken with hand-lines in two spots, one close to Port Said, the other in the middle of the Great Bitter Lake. They were all of one species, a sort of mullet, but there are no books at hand to determine the species. The mud brought up from the bottom of the Great Bitter Lake by the chain cable was absolutely devoid of any traces of life. The *Mirzapore* has been visited on her voyage by various land birds. One hen chaffinch accompanied us from Cape Finisterre to Port Said, not leaving the ship when she was anchored at Malta, and was to be seen every day hopping about the deck and feeding. At present the ship is surrounded by vast flights of flying fish. They fly generally up wind, and sometimes go as far as one hundred yards.

It is hoped that this short note may be found of some interest, and that it will be borne in mind that it is impossible to travel about with a library sufficient to determine species on the spot.

H. N. MOSELEY

MELTING AND REGELATION OF ICE

AN observation made yesterday caused me to present to my class, in a lecture on Heat this morning, the following experiment. A piece of wire gauze was laid on a convenient horizontal ring, and on this a lump of ice. A flat board was placed on the ice, and pressure was applied by means of weights put upon the board. I put 12 lbs. upon a piece of ice as large as an apple. This was done at the commencement of the lecture, and before the conclusion I found a considerable quantity of ice on the lower side of the gauze, apparently squeezed through the meshes. The temperature of the class-room was about 15° C. (59° Fah.). The experiment was continued for eight or ten hours, fresh ice being supplied when necessary to the upper side of the gauze, and, in spite of the continual surface melting and dripping away of water, a very large quantity of ice was formed below the gauze. The ice below the gauze was firmly united to that above. I tried with my hands to break away the upper from the lower, and to break either of them off at the place where the wire gauze separated them; but I was not able to do so. The ice that has passed through the meshes has a kind of texture corresponding to that of the network, and the small air bubbles appeared to be arranged in columns.

The phenomenon is a consequence of the properties, announced from theory by Prof. James Thomson, and then exemplified by an experiment; and the explanation depends on the theories put forward by him—the first (1857) founded on the lowering of the freezing point of water by pressure, and the second (1861) founded on the tendency to melt given by the application to the solid ice of forces whose nature is to produce change of form as distinguished from forces applied alike to the liquid and solid. The stress upon the ice, due to its pressure on the network, gives it a tendency to melt at the point in contact with the wire, and the ice, in the form of water intermixed with fragments and new crystals, moves so as to relieve itself of pressure. As soon as any portion of the mass is thus relieved, freezing takes place throughout it, because its temperature is reduced below that of the freezing point of water at ordinary pressures, by melting of contiguous parts. The obvious tendency of the ice under the pressure from above is thus, by a series of meltings and refreezings, to force itself through the meshes.

The next experiment that I tried I was led to by that just described. I supported a block of ice on two parallel boards, placed near to each other, and passed a loop of wire over the ice. The loop hung down between the boards, and weights were attached

to it. The first wire tried was a fine one (0·007 inches diameter) and a two-pound weight was hung on the loop. The wire immediately entered the ice, and it passed right through it and dropped down with the weight after having done so, but it left the ice undivided, and on trying it with a knife and chisel in the plane in which the cutting had taken place, I did not find that it was weaker there than elsewhere. The track of the wire was marked by opacity of the ice along the plane of passage. This opacity seemed to be due to the scattering of air from the small bubbles cut across by the wire. I have not, however, been able to try a piece of ice free from bubbles; and, from the nature of the experiment, air may very possibly pass in along the wire from the outside. I next experimented with a wire 0·024 inches diameter, weighting the loop with 8 lbs., and obtained a similar result; and, finally, I took a wire 0·1 inch diameter, and, putting a 56 lb. weight on a loop of it, I caused it to pass through the ice, and the block remained undivided. This, though it follows from theory, has a most startling effect; and during the passage of the thick wire through the ice, I was able to see the bubbles of air across which it cut rising up round its sides. I made careful trials to cut the ice with a knife in the lamina through which the wire had passed, but found no weakness there.

A string was next tried, but, as might be expected, it did not pass through the ice. I considered that the string was not a good enough conductor to relieve itself of the cold in front and pass it back to the water behind. The capillary action of the string also doubtless takes part in the production of the result. It simply indented the ice and froze into it.

On this point of the necessity for a good conductor, and for a way of relieving itself of the cold, a curious observation was made. In one case a thick wire appeared to have stopped (this requires confirmation) as if it were frozen into the ice. On examination it turned out that the ice was so placed that the water formed by the pressure of the wire had flowed away at the first, and a hole was left behind the wire. On supplying a few drops of water to the place from a small pointed bit of melting ice, the water froze instantly on coming in contact with the wire, and the wire moved forward as usual. By this I was also led to try putting a thick wire over a piece of ice having a hollow at the top, so that the wire cutting into the shoulders bridged across the hollow between them. Looking at the wire, which was in front of a window, I dropped some ice-cold water on it, and saw it freeze instantly into crystals on the parts of the wire near to the shoulders on which it was pressing. This is notable as the first experimental confirmation of Prof. Thomson's theory on the production of cold by the application of stress.

I have not yet had an opportunity of trying these experiments at a temperature lower than freezing. The amount of pressure necessary to make the wire pass through the ice would of course be very much increased as the temperature is lowered, and it would finally be impossible to cut the ice without breaking it up like any other hard solid. Indeed I saw in one case in which I had a very great weight (80 lb. or so) on a thick wire, the ice cracking in front of the wire; apparently the wire was forced too fast through the ice.

These experiments seem to me to have considerable importance in relation to the sliding motion of glaciers. The smallness of the cause has been raised as an objection to the theory of Prof. Thomson. But no one can see the experiments I have described, particularly the first, where a large quantity of ice is squeezed through the meshes of fine wire gauze under small pressure and in a short time, without feeling almost surprised at the slowness of the glacier motion.

JAMES THOMSON BOTTOMLEY

Glasgow University, Dec. 20, 1871

ELECTROPHYSIOLOGICA :

BEING AN ATTEMPT TO SHOW HOW ELECTRICITY MAY DO MUCH OF WHAT IS COMMONLY BELIEVED TO BE THE SPECIAL WORK OF A VITAL PRINCIPLE.

I.

ON a white marble slab let into the front of a house in the Strada Felice at Bologna is an inscription showing that, in this house, then his temporary dwelling-place, at the beginning of September 1785, Galvani discovered animal electricity in the dead frog, and hailing this event as the well-spring of wonders for all ages (Luigi Galvani in questa casa di sua temporaria dimora al primi di Settembre dell'anno 1785, scoperse dalle morte rane La Elettricità Animale—Fonte di maraviglie a tutti secoli). Animal electricity, well spring of wonders for all ages! Yes, said I, as I copied these words a few weeks ago, and as I went into the house repeating them to myself. Yes, still said I, after seeing what was to be seen within the house. Within the house, indeed, there was much to excite the imagination, and to make me more ready to accept these words as the sober utterance of simple truth. Still the same were the common stairs leading from the open outer door to the landing on the first floor, with its two main doors, one on each side, each one opening to a distinct set of apartments, in one of which had lived the discoverer of animal electricity; and the only change of moment was one which served to call back more vividly the memorable past—a portrait in lithograph of Galvani himself hanging upon the wall facing the stair-head. Still the same was a third and smaller door, at which the portrait seemed to be looking, and beyond which were the stairs leading to the belvedere on the roof so common in Italian houses hereabouts. Still the same were these stairs, the lower flights of uneven bricks, the upper of ricketty woodwork, unattended, scarcely swept, since the time when Galvani went up and down them afire with the discovery made in the belvedere to which they led. Still the same was the belvedere itself—the same walls, blank on one side, pierced on the three others with arched openings, two at each end, three at the front, each opening being built up breast-high so as to form the parapet—the same roof overhead with its bare rafters and tiles—and, running across each opening a little below its arched top and parallel with the parapet, the very same iron bar upon which the frogs' limbs had been suspended by copper hooks in the experiment to which the inscription on the slab outside the house refers, and about which Galvani wrote:—"Ranasitque consueto more paratas uncino ferreo earum spinali medulla perforata atque appensa, septembris initio (1786) die vesperscente supra parapetto horizontaliter collocavimus. Uncinus ferream laminam tangebatur; en motus in rana spontanei, varii, haud infrequentes! Si digito uncinulum adversus ferream superficiem premeretur, quiescentes excitabantur, et toties ferme quoties hujusmodi pressio adhiberetur." So little change was there, indeed, that, forgetting the present altogether, I could only think of this experiment in which the existence of animal electricity was divined, and of those myriad other experiments to which it had led, and by which in the end the truth had been made manifest. So absorbed was I in these thoughts that I even forgot to look through the open arches of the belvedere at the blue Italian sky and the other beauties of the prospect. And when at length I came down, I was more than ever in the mind to assent unhesitatingly to the words, "*La elettricità animale, fonte di maraviglie a tutti secoli*"—more than ever convinced that animal electricity would prove to be the key by which to unlock not a few of the secrets which are supposed to be exclusively in the keeping of life—more than ever resolved still to go on seeking for truth in the path along which I was urged to go by this conviction.

Nor was I long at a loss how to begin to carry out this resolution. I wanted to reiterate briefly and more clearly some of the things which I had said before respecting

animal electricity, and the way in which this force may do a work ascribed to life in muscular action and nervous action; and at the same time to make use of certain new facts which were not a little calculated to confirm former conclusions. I wanted to show that the same workings of animal electricity may be detected in the condition called tone, and even in growth, and that these processes, no less than muscular action and nervous action, may have to be looked upon as electrical rather than as vital manifestations. A natural way of carrying out the resolution I had formed was, indeed, to do the work ready for me; and therefore the task I have now set myself is to do this work, beginning with an attempt to set forth a new theory of animal electricity, and then proceeding to say something in turn on the way in which this theory sheds light upon muscular action, nervous action, the maintenance of the state called tone, and the process of growth in cells and certain fibres—something calculated to show that in each of these cases animal electricity may have to do much of what is commonly believed to be the work of a vital principle.

1. *On a theory of animal electricity which seems to arise naturally out of the facts.*

A current, to which the name of muscle-current is given, may easily be detected in living muscle. It may be detected by applying the electrodes of the galvanometer, the one to the surface made up of the sides of the fibres, the other to that made up of either one of the two ends of the fibres, and also, though much less clearly, by examining either of these two surfaces singly, provided only the two points to which the electrodes are applied are at unequal distances from the central point of the surface. It may not be detected, if, instead of applying them in this manner, the electrodes are applied so as to connect either the two surfaces made up of the ends of the fibres, or two points equidistant from the central point of the surface made up of the sides, or of that formed by either one of the ends of these fibres. A current may or may not be detected under such circumstances, and when it is detected its direction is such as to show that the surface made up of the sides of the fibre is positive in relation to that made up of either one of the two ends, and that the former surface is more positive and the latter more negative as the distance increases from the line of junction between these two surfaces. In this way the galvanometer makes known the existence of points of similar and dissimilar electric tension in living muscle; and the only inference from the facts would seem to be that there is a current when the electrodes are applied so as to bring together points of dissimilar tension, but not otherwise. The facts are not to be questioned. The inferences arising from them can scarcely be mistaken.

This current is to be detected in living muscle, but not in muscle which has passed into the state of rigor mortis. As muscle loses its "irritability," indeed, it ceases to act upon the galvanometer, and no trace of the current is to be met with after the establishment of rigor mortis. As a rule, too, nothing is to be noticed except a gradual failure of current; but now and then (though not in the frog) there may be a reversal in direction in the last moments preceding the final disappearance.

When muscle passes from the state of rest into that of action, there is also a change in the muscle current to which the name of "negative variation" is given by its discoverer Du Bois-Reymond. Thus, when a galvanometer is connected with the gastrocnemius of a frog, so as to respond to its muscle-current during the two states of rest and action in the muscle, the needle, which may have stood at 90°, thereabouts, during the state of rest, is seen to fall back, and take up a position at 5° or nearer still to zero, during action. This change it is which is spoken of as "negative variation." It is a change indicating, not reversal of the current, but simple weakening; for the idea of reversal, which is readily

suggested to the mind by the way in which the needle swings back past zero when the state of action is first set up, is at once corrected by the position which the needle takes up a moment or two later, and also by the fact that when the muscle-current of the *contracted* muscle is admitted into the coil of the galvanometer while the needle is resting at zero—when, that is, the experiment is not complicated by the muscle-current of the *relaxed* muscle being in the coil when the state of contraction is set up in the muscle—the needle is found to move in the same direction as that in which it moved under the current of the *relaxed* muscle, but not to the same distance from zero by a very great deal. So that, in fact, this “negative variation” of the muscle-current is nothing more than a sudden disappearance or failure of this current, and no good is gained by retaining a name which only serves to confuse and perplex.

Substituting the new quadrant electrometer of Sir William Thomson for the galvanometer, tensional changes are detected which are in every way parallel with the current changes which have been mentioned.

With this instrument, it is found that the surface made up of the sides of the fibres in living muscle, and that made up of either one of the two ends of these fibres, are in opposite electrical conditions, the ray of light marking the movement of the aluminium needle passing in the direction indicating positive electricity under the charge supplied by the former surface, and in the direction indicating negative electricity under the charge supplied by the latter surface—passing, that is to say, not in one direction only, as it would do if the needle were acted upon by charges differing, not in kind, but in degree only, but to the right in the one case and to the left in the other. It is found, indeed, not only that the surface made up of the sides of the fibres of living muscle is positive, and that made up of either end of these fibres negative; but also that the former surface is more positive and the latter more negative as the distance increases from the line of junction between these surfaces. With this instrument, too, it is found that these indications of free electricity fail *pari passu* with this failure of the “irritability” of the muscle, that they have disappeared altogether before the advent of rigor mortis, and also that there is a change which serves to point to discharge, more or less complete, when muscle passes from the state of rest into that of action. Thus—in illustration of this latter fact—if the ray of light on the scale stand at 30° under the charge supplied to the electrometer by either one of the two surfaces of living muscle during the state of rest, it will stand at 5° only, or still nearer to zero, under the charge supplied by the same surface during the state of action. The difference is always marked, and always of the same character; and, being so, the proof of discharge during action would seem to be as complete as may be, seeing that the instrument only takes cognizance of electrical changes of the nature of charge and discharge.

These, then, are the facts which may be looked upon as fundamental. There are the facts brought to light by Du Bois-Reymond through the instrumentality of the galvanometer—the muscle-current, present in living muscle during the state of rest, suddenly disappearing when the state of rest changes for that of action, gradually disappearing as muscle loses its “irritability,” and absent altogether in rigor mortis; there are the facts which I myself have been able to make out for the first time by means of the wonderfully sensitive new quadrant electrometer of Sir William Thomson—the two opposite charges of electricity, one positive, the other negative, present in living muscle during the state of rest, disappearing suddenly when this state changes for that of action, gradually disappearing before, and altogether absent in, rigor mortis. And this is all that need be said upon this subject at present.

And as in muscular so in nerve tissue, there is the

current, in this case called the nerve-current, and there are the two opposite charges, positive and negative, this current and these charges being present during life, disappearing suddenly when the state of rest changes for that of action, disappearing gradually *pari passu* with the “irritability,” and absent altogether at the time when rigor mortis has seized upon the muscles; and in truth every particular in the electrical history of the muscle is repeated with strict exactness in the electrical history of the nerve.

In these two tissues, muscle and nerve, there is no difficulty in arriving at a knowledge of these facts; in other tissues the case is different. In other tissues, indeed, all that can be said is that faint indications of electricity are to be detected during life only, and that in some of the fibrous structures there are differences between the surface made up of the sides of the fibres and that made up by either one of the two ends, which correspond to those met with in muscle and nerve.

These then being the fundamental points in the history of animal electricity, the question is as to their meaning. To what theory do they point?

In order to account for this muscle-current and nerve-current, Dr. Du Bois-Reymond supposes that the muscle-fibre and nerve-fibre (the same law applies absolutely to both) are made up of what he calls peripolar molecules—of molecules, that is to say, which are (with the exception of certain moments in which these electric relations may be reversed) negative at the two poles and positive in the equatorial belt between those poles. He supposes that the sides of the fibres are positive because the positive equatorial belts are turned in this direction, and that the two ends are negative because the negative poles of the molecules face towards the ends. He supposes also that the muscle-current and nerve-current are merely the outflowings of infinitely stronger currents ever circulating in closed circuits around the peripolar molecules of the muscle and nerve respectively. And this view no doubt has much to recommend it.

But another view may be taken of this matter—a view according to which this electrical condition of living muscle and nerve during rest is, not current, but static; and this view is that which recommends itself to my mind as in every way more simple, more comprehensive, and more to the point practically.

In taking this view the great resistance of the animal tissues to electrical conduction serves as the starting point. I assume that parts of these tissues may be bad enough conductors to allow them to act as *dielectrics*. I assume that the parts which are thus capable of acting as *dielectrics* are the sheaths of the fibres in muscle and nerve, or the cell-membrane of the contractile cells of those fibres in muscle which have no proper sheath. I assume that a charge, usually the negative, may originate in the molecular reactions of the contents of the sheath or cell-membrane, and that this charge, acting upon the inner surface of the sheath or cell-membrane, may induce the opposite charge upon the outer surface of the sheath or cell-membrane, and that in this way the sheath or cell-membrane during rest is virtually a charged Leyden-jar. I assume that this charge is discharged when the state of rest changes for that of action. I assume that the surface made up of the sides of the fibres in muscle and nerve is positive because positive electricity has been induced upon this surface, and that the surface made up of either cut-end of the fibre is negative, because the negative electricity, developed upon the inner surface of the sheath or cell-membrane, is conducted to these ends by the contents of the sheath or cell.

All that I assume, indeed, may be readily illustrated upon a small cylinder of wood, left bare at its two ends, and having its sides covered with a coating which may be charged as a Leyden-jar is charged—a threefold coating, formed of an inner and outer layer of tinfoil, with an in-

intermediate layer of gutta-percha sheeting, the latter layer projecting a little towards the two ends of the cylinder, so as to secure the necessary insulation of the inner and outer metallic surfaces; for by charging the inner layer of foil with negative electricity, this cylinder, which may be regarded as a model of a muscular fibre, is found to be, not only positive at the sides and negative at the two ends, but more positive at the sides and more negative at each end as the distance increases from the line of junction between the sides and ends. With this model thus charged, indeed, it is easy to imitate all the phenomena of the nerve-current and muscle-current, provided the electrodes of the galvanometer be applied in a suitable manner, and the charge kept up. With this model thus charged, it is also easy to imitate all the tensional phenomena of nerve and muscle which are made known by the electrometer. And thus the nerve-current and muscle-current, instead of being out-flowings of infinitely stronger currents ever circulating around peripolar molecules, may be secondary phenomena only, the accidental result of certain points of dissimilar electric tension upon the surface of the fibres of muscle and nerve being brought into relation by means of the galvanometer or the electrometer, as the case may be.

In this view, I have assumed that certain parts of nerve and muscle were sufficiently bad conductors to enable them to act as dielectrics, but I had not, it is easy to see, the firmest ground for this assumption. It was certain that these tissues were bad conductors; it was not certain that they were bad enough conductors for my purpose. Here, then, was occasion for new work—for work which must be done before I could hope to gain a secure footing for my theory; and this, therefore, was the task I set myself a few months ago, and about which I have now to say something.

In this work I have made use of a Wheatstone's Bridge having on each side resistance coils of the value respectively of 10, 100, and 1,000 B. A. units, of a set of resistance coils capable of measuring up to 1,000,000 of the same units, and of a battery consisting of six medium-sized Bunsen's cells. With this apparatus I have measured the resistance of muscle, tendon, yellow elastic ligament, brain, and spinal cord, the portion measured in each case being a parallelogram an inch in length by $\frac{1}{16}$ of an inch in breadth, formed by making a slice with a Valentin's knife, of which the blades were $\frac{1}{16}$ of an inch apart, and then cutting a strip from the slice by moving the knife, with its blades still separated to the same degree, at right angles to its surface. In order to eliminate the resistance due to secondary polarity, I measured each of these bodies at '25, '50, and '75 of the inch, as well as at the full inch, the fact being, as was pointed out by Sir Charles Wheatstone in his first great paper on the means of measuring electrical resistance, that while the resistance of a conductor increases with its length, the resistance due to secondary polarity remains the same everywhere. Thus, at '25 it is impossible to say how much of the resistance met with belongs to the body itself, and how much to secondary polarity; but not so after '25, at '50, or '75, or '10; for the resistance belonging to secondary polarity being the same at '50, '75, and '10, as at '25, it follows that by deducting the resistance at '25 from the resistance at '50, '75, and '10 the difference at each of these points will represent the resistance of the body itself between '25 and that particular point.

Of these measurements those which I made last of all will serve as well as any others for the text of what I have now to say, and these are as follows:—

	Inch.	B. A. units
Muscle (ox)	at '25 =	17,000
	'50 =	27,000
	'75 =	36,000
	'10 =	46,000

	Inch.	B. A. units.
Tendon (ox)	at '25 =	19,000
	'50 =	43,000
	'75 =	69,000
	'10 =	99,000
Yellow elastic ligament (ox)	at '25 =	160,000
	'50 =	300,000
	'75 =	820,000
	'10 =	1,000,000 and more.
Brain (ox)	at '25 =	11,500
	'50 =	16,100
	'75 =	23,000
	'10 =	32,000
Spinal cord (ox)	at '25 =	8,300
	'50 =	14,200
	'75 =	17,500
	'10 =	22,500

I had made several measurements before these, corresponding more or less closely with them in results, and I was proceeding to make others, with a view to arrive at some common mean of numbers, when I found that the resistance went on continually altering, every moment becoming higher and higher, until in the end it was beyond the reach of my means of measurement.

Thus, in the strip of spinal cord, the resistance at '25 inch, which at first was 8,300, was 180,000 in five hours, and more than 1,000,000 twelve hours later.

Thus, the resistance of the strip of brain, which at first was 11,500 at '25 inch, was 25,000 five hours later, and upwards of 1,000,000 after the still further lapse of a dozen hours.

And so, likewise, with muscle, and tendon, and yellow elastic ligament, there was a corresponding increase of resistance when the measurement was repeated at these different times after the first trial.

Nor was this the only proof of a change of this sort; for on repeating these measurements on the same specimens some days later, after they had become thoroughly dried up, I found that the very shortest length which could be got for measurement—a length so short, that the two electrodes conveying the measuring current were all but touching—gave a higher resistance than that which could be gauged by the means at my disposal.

These, then, being the facts, it was evidently useless to go on searching for any numbers which could express anything like a common mean of resistance. It was evident, indeed, that the soft tissues, one and all, apart from moisture, were to be looked upon as insulators, rather than as conductors. Nay, it was possible that they might be insulators rather than conductors even in the fresh state; for it is quite supposable that in this fresh state the walls of the fibres and cells forming these tissues may be virtually dry, with moisture on each side, not with moisture percolating from side to side, and that the degree of resistance presented by these tissues, when fresh, is not that which would be encountered if the current passed across these walls, but that which is encountered by the current in passing along their outer moistened surface. It is quite supposable that the measuring current may not pass across the walls of the cells and fibres at all, but may glide over and between them only. All this is supposable; and therefore, the facts being as they are, I am, as I conceive, at liberty to assume that the walls of fibres and cells are sufficiently non-conducting to justify me in adopting the theory which I have ventured to propose—a theory, according to which, the electrical condition of muscle and nerve during rest is, not current, but static—the sheath of the fibre, or membrane, taking its place, being always charged as a Leyden-jar is charged, except during the time of action, when there is a discharge of this charge—a theory which, to say the least, has a less

visionary foundation than that which rests on peripolar molecules seeing that it rests upon structural facts which cannot be called in question—a theory also which, as will be seen in due time, has this in its favour,—that it will simplify not a little several important problems in physiology.

C. B. RADCLIFFE

ICE-MAKING IN THE TROPICS

THE most marked example of the influence of radiation of heat on temperature is its influence on the production of artificial ice by the natives of India.

The fields in which the ice is made are low, flat, and open; and the ice is produced in large quantities when the temperature of the air is 16° or 20° F. above the freezing point; and the plan followed is an interesting example of accurate observation applied to practical purposes by a people now ignorant of science. The same process has been employed from time immemorial in India with scientific accuracy; and while the theory was explained by Dr. Wells,* the practical application was not so well understood; and this first led me to investigate the subject in India.†

The following method is employed by the natives of Bengal for making ice at the town of Hooghly near Calcutta, in fields freely exposed to the sky, and formed of a black loam soil upon a substratum of sand.

The natives commence their preparations by marking out a rectangular piece of ground 120 feet long by 20 broad, in an easterly and westerly direction, from which the soil is removed to the depth of two feet. This excavation is smoothed, and is allowed to remain exposed to the sun to dry, when rice straw in small sheaves is laid in an oblique direction in the hollow, with loose straw upon the top, to the depth of a foot and a half, leaving its surface half a foot below that of the ground. Numerous beds of this kind are formed, with narrow pathways between them, in which large earthen water-jars are sunk in the ground for the convenience of having water near, to fill the shallow unglazed earthen vessels in which it is to be frozen. These dishes are 9 inches in diameter at the top, diminishing to $4\frac{1}{2}$ inches at the bottom, $1\frac{1}{2}$ deep, and $\frac{1}{8}$ of an inch in thickness; and are so porous as to become moist throughout when water is put into them.

During the day the loose straw in the beds above the sheaves is occasionally turned up, so that the whole may be kept dry, and the water-jars between the beds are filled with soft pure water from the neighbouring pools. Towards evening the shallow earthen dishes are arranged in rows upon the straw, and by means of small earthen pots, tied to the extremities of long bamboo rods, each is filled about a third with water. The quantity, however, varies according to the expectation of ice—which is known by the clearness of the sky, and the steadiness with which the wind blows from the N.N.W. When favourable, about eight ounces of water is put into each dish, and when less is expected, from two to four ounces is the usual quantity; but, in all cases, more water is put into the dishes nearest the western end of the beds, as the sun first falls on that part, and the ice is thus more easily removed, from its solution being quicker.

There are about 4,590 plates in each of the beds last made, and if we allow five ounces for each dish, which presents a surface of about 4 inches square, there will be an aggregate of 239 gallons, and a surface of 1,530 square feet of water in each bed.

In the cold season, when the temperature of the air at the ice-fields is under 50° F., and there are gentle airs from the northern and western direction, ice forms in the course of the night in each of the shallow dishes. Persons

are stationed to observe when a small film appears upon the water in the dishes, when the contents of several are mixed together, and thrown over the other dishes. This operation increases the congealing process; as a state of calmness has been discovered by the natives to diminish the quantity of ice produced. When the sky is quite clear, with gentle steady airs from the N.N.W., which proceed from the hills of considerable elevation near Bheerboom, about 100 miles from Hooghly, the freezing commences before or about midnight, and continues to advance until morning, when the thickest ice is formed. I have seen it seven-tenths of an inch in thickness, and in a few very favourable nights the whole of the water is frozen, when it is called by the natives solid ice. When it commences to congeal between two and three o'clock in the morning, thinner ice is expected, called paper-ice; and when about four or five o'clock in the morning the thinnest is obtained, called flower-ice.

Upwards of two hundred and fifty persons, of all ages, are actively employed in securing the ice for some hours every morning that ice is procured, and this forms one of the most animated scenes to be witnessed in Bengal. In a favourable night upwards of 10 cwt. of ice will be obtained from one bed, and from twenty beds upwards of 10 tons.

When the wind attains a southerly or easterly direction, no ice is formed, from its not being sufficiently dry; not even though the temperature of the air be lower than when it is made with the wind more from a northern or western point. The N.N.W. is the most favourable direction of wind for making ice, and this diminishes in power as it approaches the due north, or west. In the latter case more latitude is allowed than from the N.N.W. to the north. So great is the influence of the direction of wind on the ice, that when it changes in the course of a night from the N.N.W. to a less favourable direction, the change not only prevents the formation of more ice, but dissolves what may have been formed. On such occasions a mist is seen hovering over the ice-beds, from the moisture over them, and the quantity condensed by the cold wind. A mist in like manner forms over deep tanks during favourable nights for making ice.

Another important circumstance in the production of ice is the amount of wind. When it approaches a breeze no ice is formed. This is explained by such rapid currents of air removing the cold air, before any accumulation of ice has taken place in the ice-beds. It is for these reasons that the thickest ice is expected when during the day a breeze has blown from the N.W., which thoroughly dries the ground.

The ice-dishes present a large moist external surface to the dry northerly evening air, which cools the water in them, so that, when at 61° , it will in a few minutes fall to 56° , or even lower. But the moisture which exudes through the dish is quickly frozen, when the evaporation from the external surface no longer continues radiative; a more powerful agent then produces the ice in the dishes.

The quantity of dry straw in the ice-beds forms a large mass of a bad conductor of heat, which penetrates but a short way into it during the day; and as soon as the sun descends below the horizon, this large and powerfully-radiating surface is brought into action, and affects the water in the thin porous vessels, themselves powerful radiators. The cold thus produced is further increased by the damp night air descending to the earth's surface, and by the removal of the heating cause, which deposits a portion of its moisture upon the now powerfully radiating, and therefore cold surface of the straw, the water, and the large moist surface of the dishes. When better radiators of heat were substituted, as glazed, white, or metallic dishes, the cold was greater, and the ice was thicker, and the dishes were heavier in the morning than the common dishes. Any accumulation of heat on their surface from the deposit of moisture is prevented by the cold dry north-west airs which slowly pass over the

* Essay on Dew, 1814.

† Experimental Essay: Jour. As. Society, Calcutta, vol. ii, p. 80.

dishes. The wind quickly dries the ground, and declines towards night to moderate airs. The influence of these causes is so powerful that I have seen the mercury in the thermometer placed upon the straw between the dishes descend to 27° , when three feet above the ice-pits it was 48° .

So powerful is the cooling effect of radiation on clear nights in tropical climates, that in very favourable mornings, during the cold season, drops of dew may sometimes be found congealed in Bengal upon the thatched roofs of houses, and upon the exposed leaves of plants. In the evening the cooling process advances more rapidly than could be supposed by one who has not experienced it himself, and proves the justness of his feelings, by the aid of the thermometer. In the open plain on which the ice is made, I have seen the temperature of the air, four feet above the ground, fall from $70^{\circ}5'$ to 57° , in the time the sun took to descend the two last degrees before his setting.

The tropical rains are succeeded by the cold season, when the night is cold, the sky quite clear, and the air becomes a bad conductor of electricity, from the dry northern winds which then prevail. This is proved by the rapidity with which evaporation proceeds, by the dispersion of clouds, and by the more evident proofs which the hygrometer exhibits. During the cold season vegetation proceeds, and electricity continues to be evolved by living bodies, and during their decomposition.

These remarks will enable us to explain the process by which the ice is prepared in Bengal.

1st. The large quantity of dry straw and moist dishes rapidly become cold, by their powerfully radiating surfaces, at the same time that the large body of dry straw strongly attracts positive electricity, and the descending currents of air deposit moisture in the dishes of water. Hence, during a cold and clear night, with airs from the N.N.W., the cooling process will advance more rapidly in proportion to the non-electric or attractive nature of the body, which, with the radiating power of the surface, regulates the cold and the quantity of dew deposited upon the body.

2nd. The high and dry situation and free exposure of the ice-fields to the sky, and the absence of all causes which could interrupt the influence of the large body of non-electrics, and the extensive surface of powerful radiating substances, sufficiently accounts for the degree of cold produced in the ice plates; and

3rd. The cool, dry north-west airs slowly pass over the ice-beds, absorbing the accumulation of moisture and of heat, which is given off by the liquefying of a large quantity of water that would otherwise accumulate over the beds; and, thus retaining the air clear and dry, allows the full operation of the other causes, particularly radiation.

T. A. WISE

NOTES

THE Academy of Sciences in Paris publishes the following telegrams received from M. Janssen. One dated Ootacamund, 18th December, 1st 6th P.M., says: "Great hydrogenous atmosphere very rare beyond chromosphere." The other, received on the 19th December by the Minister of Public Instruction, but not dated, simply says: "Eclipse observed; important results."—The Royal Academy of Sciences at Amsterdam has received the following telegram from one of its members, Dr. Oudemans, of Batavia:—"Preliminary results: Corona distinctly seen, pure white rays, dark rifts as far as the moon's limb; no outline of chromosphere; radial polarisation of Corona; no magnetic disturbances; moving shadows positively observed."

At the meeting of the French Academy, held on Saturday last, to fill up the four vacant chairs, M. Thiers, M. de Remusat, Minister for Foreign Affairs, and M. Dufaure, Minister of Justice were present and voted. The first election was for a suc-

cessor to Montalembert, and the Duc d'Aumale received 28 votes, one blank vote being recorded. For M. Villemaine's chair there were three candidates, M. Littré, who obtained 17 votes; M. Taillandier, 9; and M. de Viel Castel, 3. There were six candidates for M. Prévost-Paradol's chair. M. Camille Rousset had 17 votes; M. de Viel Castel, 7; M. de Mazade, 3; M. de Lomenie, 1; M. Taillandier, 1; and M. Mary-Lafon, 0. The choice of a successor to Prosper Mérimée was only made after two ballottings. At the first essay M. Edmond About obtained 13 votes; M. de Lomenie, 13; M. de Viel Castel, 2; M. de Mazade, 1; and M. Mary-Lafon, 0. At the second ballot M. de Lomenie received 15 votes, and M. Edmond About 14. Previous to the election a protest in the form of a lengthy pamphlet was distributed among the Academicians by the Bishop of Orleans, who, while professing the utmost respect for the personal character of M. Littré, declared that now, as in 1863, he opposed the admission into the Academy of one who in his writings was the defender of Materialism, Atheism, and Socialism. We learn that in consequence of M. Littré's election, M. Monseigneur Dupanloup has resigned his seat in the Academy.

WE greatly regret to hear of the death, announced by telegram, from choleraic diarrhoea, of the Venerable John Henry Pratt, M.A., Archdeacon of Calcutta. He was educated at Caius College, Cambridge, where he took his B.A. degree in 1833, when he was third wrangler, the Masters of Christ's and Sidney Sussex Colleges being also wranglers, with Dr. Boustead, afterwards Bishop of Lichfield. In 1838 he was appointed to a chaplaincy in connection with the East Indian Company, and in 1850 was nominated to the Archdeaconry of Calcutta, which he held up to the time of his death. He was well-known for his researches of the interior structure of the earth, and had been a frequent contributor to our columns.

DR. GUSTAV RADDE, Director of the Natural History Museum at Tiflis, has just returned to that town from an interesting journey to the head waters of the Euphrates. Mr. H. E. Dresser has received a letter from him, dated Tiflis, Dec. 14, from which we translate the following extract, viz.:—"Early in August I ascended, in company with Dr. Sievers, a young geologist, the Great Ararat, and we reached an altitude of 14,233 feet above the sea level. Our journey extended over three months, and we have brought back a splendid botanical collection, many good insects, and geological specimens. You will read full particulars ere long in Petermann's 'Mittheilungen.' As regards ornithology, I have not, I am sorry to say, time now to write further respecting the good materials we gathered together, and am just leaving home for another month."

THE Professors to the Newcastle-on-Tyne College of Physical Science have determined to institute evening classes, to commence immediately after the winter vacation, for the purpose of giving instruction in their respective subjects to persons who are unable to attend their day classes. The Professors wish it to be understood that the instruction given in these classes will be such as to require a certain amount of real study on the part of those who attend them.

THE Curator of the Clifton College Museum, Mr. Barrington Ward, has issued a circular asking for donations, to which we are glad to call attention. The following extract will show the very wise limitation placed on the acceptance of specimens:—"It has been decided, with the approval of the Head Master, that the museum shall be essentially a British one, and shall illustrate the natural history and antiquities of our land by good specimens, systematically arranged, under the departments of zoology, botany, geology, mineralogy, and archaeology. In addition to this there will be a collection of rare and curious objects, derived from all sources, which may be considered useful for the purposes of scientific teaching, and a large typical

series to be used at the lectures and demonstrations given in the College on Comparative Anatomy and other branches of Natural History. The committee of management will only accept of such specimens as can be classed under some one of these heads." In the Botanic Garden attached to the College nearly a thousand species of hardy herbaceous plants are now grown.

WE have received the Preliminary Report by Mr. Sidney I. Smith, on the dredging in Lake Superior; and a reprint from the *American Journal of Science and Art* for December, of Mr. S. I. Smith and Mr. A. S. Verrill's notice of the Invertebrata dredged in the same expedition. The main facts of these reports are already before our readers.

A SOCIETY of Arts, Sciences, and Letters, has just been started at Winona, Minnesota, in connection with the first State Normal School in that place, having for its object the collection of facts and materials looking toward the determination of the natural history, archaeology, and general literature of the United States.

DR. HOY, in a paper read before the Wisconsin Academy of Sciences, Arts, and Letters, remarks, in reference to the mammals of Wisconsin, that the elk existed in that State as late as 1863, but is now probably extinct. The moose is still found in considerable numbers. The last buffalo was killed in 1832. Antelopes were also found in Wisconsin in the time of Father Hennepin, although now, of course, driven far to the west. Most of the wild animals are diminishing very rapidly in number, the panther and deer being almost exterminated. The otter and beaver, however, are very persistent. The last wild turkey was killed in 1846 near Racine.

A SCIENTIFIC commission in the interest of the Government of Peru has lately been investigating the guano deposits of the Lobos Islands; and it is reported that the result of their inquiries has been very satisfactory, and that immense quantities of very rich guano, equal, if not superior, to that of the Chincha Islands, have been observed. The analyses of samples are said to have yielded over 13 per cent. of ammonia. Should this be the fact, Payta, as being the nearest port, will probably become a place of considerable importance.

THE Report presented to, and read before, the Board of Visitors appointed by Government for the Royal Observatory, Edinburgh, after summarising the work done at the Observatory during the year, calls attention to the very inefficient manner in which the establishment is provided with funds for its necessary work, and to the scanty salary of its director and assistants. The Board of Visitors estimates the increased annual expenditure necessary to ensure the efficient working of the establishment at 1,050*l.*, including 300*l.* increase in the salary of the Astronomer Royal. The report is accompanied by a coloured plan of the Observatory, showing the position of the various instruments, and diagrams of the quarterly means of the earth thermometers from 1837 to 1869; annual mean temperatures, for four several sub-annual epochs, of the rock at the Observatory in the same years; annual means of Schwabe's sun-spots, the earth thermometers, and others at Edinburgh; and eleven-year means for every successive year, from 1842 to 1864, of Schwabe's sun-spots and Edinburgh earth temperatures.

THE seventh Report of the Board of Visitors of the Observatory at Victoria, with the Annual Report of the Government Astronomer, is printed. The report of the buildings and instruments is in every respect satisfactory.

MR. W. H. ARCHER has brought down his records of patents and patentees for the colony of Victoria to the end of 1869; and the Reports of the Mining Surveyors and Registrars for the same colony are printed for the quarter ending June 30, 1871.

THE Report of the New Zealand Institute for its fourth session, 1871, contains the Annual Address, delivered by Sir G. F. Bowen, and a list of donations and deposits in the Museum, and the Laboratory Report for 1870-71. Captain Hutton has prepared a complete catalogue, with a diagnosis, of each species of bird in New Zealand; and arrangements have been made for the publication of similar catalogues of the insects, fishes, and other branches of zoology in the island.

WE have received the last two Annual Reports of the Plymouth Institution and Devon and Cornwall Natural History Society, forming together vol. iv. of its Transactions. Though many of the papers and lectures reported refer to subjects which do not come within our scope, the volumes bear evidence of the zeal and success with which the natural and physical sciences are pursued in the Western counties. Among the papers specially deserving of mention, we may notice, "Degeneration of our Deep-sea Fisheries," by Mr. J. N. Hearder; "The Fulgorator," a new electrical apparatus for producing electric sparks of very great length, by the same; "Rain," by W. Pengelly, F.R.S.; "Mistletoe on the Oak," by T. R. Archer Briggs; "The principles on which ships' sail-carrying power and steadiness in a sea-way depend," by W. Froude, F.R.S.

A PROSPECTUS is issued of a third enlarged and improved edition of Von Cotta's "Geology of the Present." Special reference will be made in this edition to the bearing on geological questions of the recent discoveries of Darwin, Mayer, and Helmholtz.

THE first number lies on our table of "The Mining Magazine and Review; a Monthly Record of Mining, Smelting, Quarrying, and Engineering," edited by Mr. Nelson Boyd. The principal articles in this number are—"The Coal Commission," by the editor; "Boiler Explosions," by E. B. Marten; "The Importance of Nitro-glycerine Explosives for Underground Quarrying Purposes," by S. J. Mackie; and "The Progress of Mineralogy," by F. W. Rudler. It contains also reviews, records of scientific progress, and miscellanea.

A LITTLE pamphlet by Mr. J. G. Fitch, entitled "Methods of Teaching Arithmetic," a lecture addressed to the London Association of Schoolmistresses, and published at the request of the Association, deserves a far wider circulation than among schoolmistresses only. We venture to say that if the admirable plan suggested in the lecture were generally adopted by teachers, of explaining in a rational manner the principles of the simple rules of arithmetic, which are generally learned by rote without the least exercise of intelligence on the part of either teacher or pupil, the teaching of arithmetic would soon cease to be the drudgery which it now is in both boys' and girls' schools, and the results, as exemplified by the reports of the Cambridge examiners and elsewhere, would be very different.

THE "Proceedings of the South Wales Institute of Engineers," Vol. vii., No. 4, contains an important paper by Mr. Thomas Joseph, "On Colliery Explosions in the South Wales Coal Field," which is also reprinted in a separate form. We find in it also many other papers and discussions of value to the engineering and coal interests.

MR. E. PARFITT reprints from the "Transactions of the Devonshire Association for the Advancement of Science, Literature, and Art" two interesting papers—"The Fauna of Devon, Part vii.: Cirripedia," and "On the Boring of Molluscs, Annelids, and Sponges into Rock, Wood, and Shells."

WE have received from Messrs. Nelson and Sons some specimens of Pictorial Natural History, consisting of packets of cards with coloured pictures of birds and some short account of each appended; they are as a series unusually good and elegant,

though of unequal merit. Any of them would make a charming present for an intelligent child.

ON November 10 there was an earthquake in Salvador in Central America, and on the 12th a stronger one. At Simla there was an earthquake on November 25. Two sharp shocks were felt at Macedonia on November 26 at 11 P.M.

WHAT is called the Iquique earthquake took place on Oct. 8, at 1 A.M. Although alarming and lasting two minutes, with a terrible shaking of the earth, first vertical and afterwards oscillatory, it did no damage at Iquique. It was, however, simultaneously felt elsewhere, and has destroyed or damaged the towns of Tarapaca, Usmagama, Guasquina, Pica, Matilla, and the village of Pachica. Some persons were injured, but only two lost their lives.

AT a recent meeting of the Scientific Committee of the Horticultural Society, a letter was read from Mr. Anderson-Henry (printed in the *Gardeners' Chronicle* for Dec. 9), in which he gave some curious results of his observations on climbing plants. Mr. Henry stated that certain climbers evince a partiality for some other species, stretching out their tendrils or branches so as to come in contact with them, while to other species they have as strong an aversion, avoiding them and never touching them, though they may run up the same wall side by side. The subject is a curious one, and deserves further investigation.

"THE Fortunate Isles," translated from the French of Ogier, is an account of the Canaries. A chapter on the celebrated dragon tree contains the two passages here transcribed. Written apparently in sober earnest, they are, perhaps, not the least remarkable contribution to the scientific literature of the year now ended. "It is an undoubted fact that before the great Mediterranean deluge, and to a certain point even after it, strange creatures brought forth in transitional periods, inhabited the marshy grounds or those shallow seas which still remained warm. This epoch, called by modern geologists the Reptile Period, produced creatures belonging at once to the animal, vegetable, and mineral kingdoms, or to two only; monstrous products of creative forces; birds, quadrupeds, fish, plants, reptiles, all at once, either united or distinct; the greater number of these have been restored for us by geologists. . . . The dragon has existed. The first men saw the last survivors of these prodigious creatures, and the memory of them has been preserved. The struggles of mankind with the mighty creatures which overran the earth must have been terrible. The excessive alarm of men possessing no weapons in the first ages, gave rise to the traditions of formidable beings attacking mankind and destroyed by the demi-gods, strong and brave men."

FROM the *Elizabeth Daily Journal* of New Jersey of Nov. 28 we have a marvellous story of a carrier pigeon, which we commend to the notice of Mr. Tegetmeier. It performed the journey from Sopus Farm, Warren Co., N.J., to Sardusky Ohio, a distance of 400 miles, in exactly an hour, and its condition on its arrival at the latter place is thus described:—"I found the greatest excitement had followed the arrival of the pigeon. Mr. Smythe told me that at precisely two o'clock the bird came like an arrow into his house. His movement was more like a blue streak than a well-defined bird. He seemed but little exhausted, although nearly all the feathers were off his body, except the small patch near on his back by the gutta-percha which fastened the note. A few miles more would have worn every feather from his wings, and then he would have to depend upon the momentum already acquired to carry him on his journey, and to steer by a tailless rump, and perhaps be killed in attempting to alight." No wonder the owner offers to match this pigeon "when he has grown a new suit of feathers" for 1,000 dollars against any carrier pigeon that has not done this distance in an equal time.

PERIODICITY OF SUN-SPOTS*

IN the short account of some recent investigations by Prof. Wolf and M. Fritz on Sun-spot phenomena, which has been published lately in the "Proceedings of the Royal Society" (No. 127, 1871), it was pointed out that some of Wolf's conclusions were not quite borne out by the results which we have given in our last paper on Solar Physics in the *Philosophical Transactions* for 1870, pp. 389-496. A closer inquiry into the cause of this discrepancy has led us to what appears a definite law, connecting numerically the two branches of the periodic sun spot curve, viz., the time during which there is a regular diminution of spot-production, and the time during which there is a constant increase.

It will be well, for the sake of clearness, to allude here again, as briefly as possible, to Prof. Wolf's results before stating those at which we have arrived.

Prof. Wolf has previously devoted the greater part of his laborious researches to a precise determination of the mean length of the whole sun-spot period, but latterly he has justly recognised the importance of obtaining some knowledge of the average character of the periodic increase and decrease. Hence he has, as far as he has been able to do so by existing series of observations, and his peculiar and ingenious method of rendering observations made at different times and by different observers comparable with each other, endeavoured to investigate more closely the nature of the periodic sun-spot curve, by tabulating and graphically representing the monthly means taken during two and a half years before and after the minimum, and applying this method to five distinct minimum epochs, which he has fixed by the following years:—

1823·2
1833·8
1844·0
1856·2
1867·2

In a table he gives their mean numbers, expressing the solar activity, arranged in various columns; and arrives at the following results:—

(1) It is shown now with greater precision than was previously possible, that the curve of sun-spots ascends with greater rapidity than it descends. The fact is shown in the subjoined diagram, which it may be of interest to compare with the curves given previously by ourselves in the above-mentioned place. The zero-point in this diagram corresponds to the minimum of each period; the abscissæ give the time before and after it, viz., two and a half years, or thirty months; the ordinates express the amount of spot-production in numbers of an arbitrary scale. The two finely dotted curves are intended to show the actual character of a portion of two periods only, viz., those which had their minima in 1823·2 and 1867·2; the strongly dotted curve, however, gives the mean of all periods (five) over which the investigation extends.

(2) Denoting by x the number of years during which the curve ascends, and presuming that the behaviour is approximately the same throughout the whole period of 11·1 years as during the five years investigated, we have the proportion

$$x : 11·1 = x : 1 : 2,$$

whence

$$x = 3·7,$$

or the average duration of an ascent is 3·7 years, that of a descent 7·4 years.

(3) The character of a single period may essentially differ from the mean, but on the whole it appears that a {retarded | accelerated} descent corresponds to a {retarded | accelerated} ascent. Thus the minimum of 1844·0 behaved very normally; but that of 1856·2, and still more that of 1823·2, shown in the following diagram, presents a retarded ascent and descent; on the other hand, the minimum of 1833·8, and still more in that of 1867·2, also shown in the diagram, both ascent and descent are accelerated.

Finally Prof. Wolf arranged in the manner shown in the following table the successive minima and maxima, in order to arrive at some generalisation which might enable him to foretell the general character and length of a future period. Taking the absolute differences in time of every two successive maxima, and

* Abstract of paper read before the Royal Society December 21, 1871. "On some recent Researches in Solar Physics, and a Law regulating the time of duration of the Sun-spot Period." By Warren De La Rue, F.R.S., Balfour Stewart, F.R.S., and Benjamin Loewy, F.R.A.S.

the mean differences of every two alternating minima, he shows that the greatest acceleration of both maximum and minimum happens together. This result strengthens our own conclusions, to be immediately stated, by new evidence, as it is derived from observations antecedent to the time over which our researches extend.

Minima.	Differences of alternating Minima.	Means.	Maxima	Differences of successive Maxima.
1810.5			1816.8	
1823.2	23.3	11.65	1829.5	12.7
1833.8	20.8	10.4	1837.2	7.7
1844.0	22.4	11.2	1846.6	11.4
1856.2	23.2	11.6	1860.2	11.6
1867.2				

From this Prof. Wolf predicts for the present period a very accelerated maximum—a prediction which seems likely to be fulfilled.

Comparing now M. Wolf's results with our own, it must not be overlooked, in judging of the agreement or discrepancy of these two independently obtained sets, that our facts have been derived from the actual measurement and subsequent calculation of the spotted area from day to day since 1833, recorded by Schwabe, Carrington, and the Kew solar photograms, which measurements are expressed as millionths of the sun's visible hemisphere, while the conclusions of M. Wolf are founded on certain "relative numbers," which give the amount of observed spots on an arbitrary scale, chiefly designed to make observations made at different times and by various observers comparable with each other. This will obviously, in addition to the sources of error to which our own method is liable, introduce an amount of uncertainty arising from errors of estimation, and the possibility of using for a whole series an erroneous factor of reduction. Nevertheless we shall find a very close agreement in various im-

portant results, and this seems a sufficient proof of the great value and reliability of M. Wolf's "relative numbers," especially for times previous to the commencement of regular sun observations.

The following is a comparison of the data of periodic epochs, as fixed by ourselves and M. Wolf:—

Minima epochs.	I.	II.	III.	IV.
De La Rue, Stewart, and Loewy	1833.92	1843.75	1856.31	1867.12
Rudolf Wolf	1833.8	1844.0	1856.2	1867.2
Maxima epochs.	I.	II.	III.	
De La Rue, Stewart, and Loewy	1836.98	1847.87	1859.69	
Rudolf Wolf	1837.2	1846.6	1860.2	

It will be seen from this comparison that only one appreciable difference occurs, viz., in the maximum of 1847, which M. Wolf fixes nearly one and a quarter years before our date.

The mean length of a period is found by us to be 11.07 years, which agrees very well with M. Wolf's value, viz., 11.1 years.

We found the following times for the duration of increase of spots during the three periods, and for the corresponding decrease, or for ascent and descent of the graphic curve, beginning with the minimum of 1833:—

	Time of ascent.	Time of descent.
I.	3.06 years.	6.77 years.
II.	4.12 "	8.44 "
III.	3.37 "	7.43 "
Mean	3.52 "	7.55 "

Prof. Wolf gives 3.7 years and 7.4 years for the ascent and descent respectively; and considering that he derived these numbers only from an investigation of a portion of each period, the agreement is indeed surprising, and would by itself suggest that the times of ascent and descent are connected by a definite law.

M. Wolf has expressed in general terms the following law with reference to this relation of increase and decrease of spots:—

"The character of a single period may essentially differ from the mean behaviour, but on the whole it appears that a { retarded } descent corresponds to a { retarded } ascent."

We, on the other hand, have, by an inspection of our curves (*vide* Phil. Trans. 1870, p. 393), been induced to make the following remark on the same question:—

"We see that the second curve, which was no longer in period as a whole than either of the other two, manifests this excess in each of its branches, that is to say, its left or ascending branch is larger as a whole than the same branch of the two other curves, and the same takes place for the second or descending branch. On the other hand, the maximum of this curve is not so high as that of either of the other two—in fact, the curve has the appearance as if it were pressed down from above and pressed out laterally so as to lose in elevation what it gains in time."

Although both statements appear to lead up to the same conclusion—viz., that ascent and descent are connected by law—still they differ essentially in this respect, that if A, B, C represent the three following consecutive events, descent, ascent, descent,

Prof. Wolf's law refers to the connection between A and B, while our remark refers to B and C. We consider two successive minima as the beginning and end of a single period, while M. Wolf, at least in this particular research, places the minimum within the period, and compares the descent from the preceding maximum with the ascent to the next one.

We have considered the connection thus indicated of sufficient importance to apply to it the following test. If, using the previous notation, a definite relation exists between A and B, the ratio of the times which the events occupy in every epoch ought to be approximately constant; similarly with respect to B and C; and this ratio should not be influenced by the absolute duration of the two successive events. It is clear that the greater uniformity of these ratios will be a test of their interdependence. The following is the result of the comparison:—

a. Prof. Wolf's law: comparison of A and B.

Periods.	Duration of descent (A).	Periods.	Duration of ascent (B).
I. 1829'5 to 1833'8	4'3 years	1833'8 to 1837'2	3'4 years.
II. 1837'2 to 1844'0	6'8 "	1844'0 to 1846'6	2'6 "
III. 1846'6 to 1850'2	9'6 "	1850'2 to 1860'2	2'0 "
Ratio $\frac{A}{B}$.		Difference from mean.	
I. 1'265	Mean 2'093	{ -0'728	
II. 2'615		{ +0'522	
III. 2'400		{ +0'307	

These differences from the mean are so considerable that in the present state of the inquiry a connection between any descent and the immediately succeeding ascent appears highly improbable. A very new and apparently important relation seems, however, to result from a similar comparison of any ascent and the immediately succeeding descent, or between B and C.

b. Comparison of B and C.

Periods.	Duration of ascent (B).	Periods.	Duration of descent (C).
I. 1833'92 to 1836'98	3'06 years	1836'98 to 1843'75	6'77 years
II. 1843'75 to 1847'87	4'12 "	1847'87 to 1856'31	8'44 "
III. 1856'31 to 1859'69	3'38 "	1859'69 to 1867'12	7'43 "
Ratio $\frac{C}{B}$.		Difference from mean.	
I. 2'212	Mean 2'151	{ +0'061	
II. 2'044		{ -0'107	
III. 2'198		{ +0'047	

PROF. AGASSIZ'S EXPLORING EXPEDITION*

WE have already announced the departure of the United States Coast Survey exploring steamer, *Hassler*, upon that scientific mission which, under the direction of Prof. Agassiz, will doubtless be productive of very important results. Just before starting on the expedition, Prof. Agassiz addressed a communication to the Superintendent of the Coast Survey, in which he ventured to assume the character of a prophet by stating in advance what it was probable would crown their efforts in the way of discovery.

The Professor makes this communication in the hope of showing within what limits natural history has advanced toward that point of maturity when science may anticipate the discovery of facts. Basing his expectations upon the ascertained principles of science, and taking into consideration the relationships between different forms of animal life, and the succession of geological epochs, and in view of the very interesting results of later deep-sea dredging expeditions in the North Atlantic, he anticipates the discovery, "from the greater depth of the ocean, of representatives resembling those types of animals which were prominent in earlier geological periods, or bear a closer resemblance to younger stages of the higher members of the same types, or to the lower forms which take their place nowadays."

Making no suggestion in regard to mammals, he remarks that if reptiles exist in the deep waters, they must be only such as are related to the extinct types of the Jurassic periods, such as the ichthyosaurs, plesiosaurs, and pterodactyles; but even of these he thinks there is very little probability that any representatives are still alive.

Among the fishes he expects to discover some marine representatives of the order of ganoids of the principal types known from the secondary zoological period. Among the sharks he thinks he shall find new forms allied to *Cestracion*, or *Ehyodon*,

or *Odontaspis*, as also new genera of chimæroids; and among ordinary fishes the allies of *Beryx*, *Elops*, &c. It is among the molluscs and radiates that objects of the greatest interest will probably be met with: and chief among these will be nautiloid cephalopods—perhaps even ammonites—and forms only known hitherto in the fossil state. Among *Accephala* he anticipates the discovery of a variety of forms resembling those from the Jurassic and Cretaceous deposits; while *Ruditæ* will take the place of oysters, and brachiopods be found very abundant.

Among *Crustacea* it is not at all impossible that forms may be found resembling trilobites; while among echinoderms he confidently expects to meet with spatangoids approaching *Holaster*, and others akin to *Dysaster*, &c.

A careful comparison of the members of the deep-sea fauna of the northern and southern hemispheres will probably prove of the greatest interest, and, judging from the peculiarities of the land and shore fauna of Australia, it is likely that the adjacent deep-sea animals will be equally divergent, and will represent remarkable forms, and especially of an extremely antique type.

The Professor also hopes that much light will be thrown upon the subject of the geology of the southern hemisphere, and upon the general features of the drift, since all the phenomena related to the glacial period must be found in the southern hemisphere with the same essential characteristics as in the northern, yet with this difference, that everything must be reversed; that is, the trend of the glacial abrasion must be from the south northward; the lee side of the abraded rocks must be on the north side of hills and mountain ranges, and the boulders must have been derived from rocky exposures lying to the south of their present position. This point, however, must be established by observation. The Professor thinks this will be found to be the case, with the exception, perhaps, of the present glaciers of Tierra del Fuego and Patagonia.

In reply to the possible inquiry as to what the question of drift has to do with deep-sea dredging, he remarks that the connection is closer than may at first appear. If drift is not of glacial origin, but the product of marine currents, its formation at once becomes a matter for the Coast Survey to investigate; but he expresses the belief that it will be found that, so far from being accumulated by the sea, the drift of the lowlands of Patagonia has been worn away to its present extent by the continued encroachment of the ocean, in the same manner as the northern shores of South America and of Brazil have been.

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie, clix., August 1871. Fittig and Remsen communicate a second paper "On the Constitution of Piperine and its decomposition products, Piperic Acid and Piperidine," in the former paper two oxidation products were described, piperonal and piperonylic acid, which stand to each other in the relation of aldehyde and acetic acid. In the present communication several new reactions of these substances are described.—The second note, "A Reaction of free Phenol-hydroxyls," shows that the benzene derivatives, containing hydroxyl associated with this nucleus, give colours with a neutral solution of ferric chloride; the intensity of the colour produced seems to bear some proportion to the number of free hydroxyl atoms, the more intense colours being produced by bodies containing more than one hydroxyl.—A paper "On the relations between the Glycerin and Allyl compounds," by Huebner and Mueller follows. They show that the dichlorhydrin prepared by Berthelot's method is a mixture of two isomeric bodies, one of which boils at 174° and can be obtained in a pure state by the action of hydrochloric acid on epichlorhydrin, the other boils at 182° and is identical with dichlorallyl alcohol. Both of these compounds yield allyl alcohol when acted on by sodium in the presence of ether. Kraut and Popp have found that if sodium amalgam containing 3 per cent. sodium is placed in potassic hydrofate solution, hard cubes are formed, which, however, possess no definite composition; by the action of sodic hydrate solution long needles are obtained, having the composition $\text{Na}_2\text{Hg}_{12}$.—A lengthy paper by Hoffmeister follows "On Phenyl Ether and Diphenyl oxide." The former is prepared by the action of nitrous acid on aniline sulphate, the product from which is mixed with phenol when nitrogen is evolved and phenyl ether formed. It can also be produced by the dry distillation of cupric benzoate. Diphenyl oxide is produced by acting on phenol with phosphoric chloride, and again acting on

* Reprinted from advance sheets of *Harper's Weekly*, by permission of the Editor.

the product with potassic hydrate. A number of substitution products of the two bodies have been prepared, and are here described.—The next paper is "On the Conversion of Acetone into Lactic Acid," by Linneanen and Zotta. This is accomplished by heating dichloroacetone with water to 200°, when a considerable proportion of lactic acid is obtained. Ladenburg has prepared stannic triethyl phenyl by the action of sodium on bromobenzol, and stannic triethyl iodide, mixed with ether. It is a colourless liquid, boiling at 254°, which is easily oxidised in the air; it reduces an alcoholic solution of silver nitrate, diphenyl being produced in the reaction. Hydrochloric acid forms with it, benzole and stannic triethyl chloride.—An interesting paper by Friedel and Ladenburg, "On Silico-propionic Acid," follows. By the action of absolute alcohol on silicic chloride, the chloride of triethylsilicic acid is obtained; sodium added to this compound, mixed with zinc ethyl, yields, on heating, ethyl orthosilico-propionate, $\text{SiC}_2\text{H}_5(\text{OC}_2\text{H}_5)_3$. Silico-propionic ether, on treatment with aqueous potassic hydrate, yields silico-propionic acid. It is a white powder resembling silica, from which it is easily distinguished by being combustible. It is soluble in hot potassic hydrate solution, but insoluble in boiling sodium hydrate. This acid is the first representative of a new series of acids, containing the group SiO_2H in the place of CO_2H .—Translations of two papers by C. E. Monroe follow, the originals of which have already appeared in the American Journals.—The number concludes with a short note "On the Preparation of Creatinine hydrochloride from urine," by K. Maly. It is purified by combining it with mercuric chloride and decomposing the compound with sulphuretted hydrogen.

SOCIETIES AND ACADEMIES

LONDON

Anthropological Institute, January 1.—Sir John Lubbock, Bart, F.R.S., President, in the chair.—Messrs. J. Thallon and J. Jeremiah, jun., were elected members.—Mr. C. Staniland Wake read a paper entitled "The Adamites." The object of this paper is to show, by reference to evidence extraneous to the Hebrew Scriptures, what peoples are entitled to be classed as Adamites. The name of the primitive race from which the Chaldeans sprang—the *Akkad*—proves that they must be thus classed. *Akkad* would seem to mean "sons of Ad;" the first syllable of the word being the same as the Gaelic *Adh* or *Ach*. The first Babylonian dynasty of Berosus was Median; and Sir Henry Rawlinson says that the name by which the Medes are first noticed on the Assyrian monuments is *Mad*. This people, the initial letter of whose name may be treated as a prefix, was doubtless the primitive stock from which the *Akkad* were derived. The Medes had also the distinctive title *Mir*; and many of the Aryan peoples appear to have retained a remembrance of the traditional *Ad*. The first part of the Parsee work known as *The Dastur* is called "the Book of the Great *Ad*," i.e., Father *Ad*. The Puranas of the Hindus refer to the legendary king, *It* or *Ad*, who is supposed to be the same as the Greek *Adas*. The primitive Celtic race of Western Europe was called *Gaid*, i.e., the progeny of Gaid or Aid, who may be identified with *Diu*, the mythical ancestor, according to Caesar, of the Gauls. *Diu* (the Greek *Hada*) was also "Lord of the Dead" among the Chaldeans, and may well, therefore, have been the same as the legendary ancestor *Ad*. Among Hamitic peoples, the original Arab stock trace their first origin to Father *Ad*, who is probably referred to also in the name of the Egyptian deity, *At-um*. The paper also mentions certain facts showing that the name of the legendary ancestor of the Adamites may be traced in the names of the deities of Turanian and American peoples, and also among the Polynesian Islanders, whose word for "spirit" is *atua*, or *akua*, and whose Great Ancestor is called *Tu-ata*. Dividing all the races of mankind, according to the simple classification of Retzius, into brachycephali and dolichocephali, the conclusion arrived at by the paper is, that *Ad* was the legendary ancestor of the former, the Adamites, therefore, embracing all the actually brachycephalic peoples, and those whose brachycephalism has been lost by intermixture with the long-headed stock. The Adamites extend through the whole of the northern hemisphere, and are found in various parts of the southern hemisphere, on both the old and the new continents. The names "Adam" and "Eve" were, however, merely expressions of the philosophical notion of the ancients that the male and female principles pervade all nature,

and originated all things and personifications of the ancestral idea in relation to the human race.

Chemical Society, Dec. 21, 1871.—Prof. Williamson, F.R.S., vice-president, in the chair.—After the usual business of the society had been transacted, the chairman announced that the celebrated Italian chemist, Prof. Canizzaro, had consented to deliver the Faraday lecture. A paper was then read by Mr. H. Bassett, "On Eulyte and Dyslyte," two beautifully crystalline compounds obtained by the action of nitric acid on citraconic acid, a product of the dry distillation of citric acid. Both these substances contain nitrogen, but owing to the comparatively small quantity obtained, namely, less than two ounces from thirty pounds of citric acid, the author has, as yet, been unable thoroughly to investigate their nature.—Prof. H. E. Armstrong also read a paper "On the Nitration of the Dichloro-Sulphonic Acids," being a continuation of his researches on the isomeric nitrochloro-phenols and their derivatives; after which the meeting adjourned until January 18, 1872.

PARIS

Academy of Sciences, Dec. 18, 1871.—M. Chasles read a continuation of his theorems relating to the harmonic axes of geometrical curves, and presented a note by M. Halphen on right lines which fulfil given conditions.—M. H. Resal presented a memoir on the conditions of resistance of a fly-wheel, and M. Combes a note by M. Haton de la Goupillière on the transformation of the potential by reciprocal radii vectors.—Telegrams received from M. Janssen, with regard to his solar observations at Ootacamund, were communicated to the Academy.—Several members referred to the prevalence of cold during the first half of the month of December 1871.—M. Delaunay called attention to the remarkable concurrence of a change of barometric pressure with an alteration in the temperature of different parts of Europe between the 6th and 9th of December, the latter date showing the maximum of cold at Paris. The great cold of the 9th of December was also the subject of a note by M. E. Becquerel, who gives a minimum temperature of $-25^{\circ}5\text{C}$. ($= -13^{\circ}9\text{F}$.) at Montargis, and of $-27^{\circ}5\text{C}$. ($= -17^{\circ}5\text{F}$.) near Courtenay in the department of the Loiret. M. C. Sainte-Claire Deville remarked upon the concordance of this statement of M. E. Becquerel's with the minimum of -26°C . ($= -14^{\circ}8\text{F}$.) recorded at Nemours. He also presented a table of minima obtained at various places in France from 7th to 15th December.—MM. Becquerel presented a memoir on the influence of snow on the temperature of the soil at various depths, according as it is covered with turf or denuded, founded chiefly on observations made from the 5th to the 15th December. The authors found that the temperature under the turfed soil, within two or three centimetres of the surface, was always above 0°C . ($= 32^{\circ}\text{F}$.), and as constantly below that point in the naked soil.—M. Pasteur presented a note on a memoir by M. Liebig, relating to fermentation, in which he defended his views as to the nature of the phenomena of fermentation from certain criticisms upon them published by Prof. Liebig. Upon this subject M. Fremy also spoke at considerable length in opposition to M. Pasteur, who replied.—M. Bussy communicated a note by M. E. Bourgoin on the complex nature of cathartine, in which the author states that this substance, regarded as the active principle of senna, is in reality composed of three distinct substances, namely, chrysophanic acid, a dextrogyrous glucose, and a new principle to which he gives the name of chrysophanine.—M. Daubrée communicated a note by M. F. Gonnard, on the dolerites of the Chaux de Bergonne and the zeolites which they contain. In this paper the author ascribes very peculiar magnetic properties to the solid dolerite of this locality, and states that the cavities of its lower amygdaloidal parts contain three zeolites (christianite, phacolite, and mesole).—M. Trécul presented a note on the remarkable arrangement of the stomata in various plants, and especially in the petiole of ferns, in which he mentioned the occurrence of stomata upon the piliform appendages of the petiole in *Phileodendron Lindemannianum*, and noticed their existence in unusual positions in many ferns.—A note by M. P. Bert, on the influence of different colours on vegetation, was communicated by M. Milne-Edwards. His general results are as follows:—green is nearly as fatal to plants as total darkness, red is very injurious, and yellow less so than red, but more so than blue, but any colour taken isolatedly is injurious to plants.

December 26, 1871.—A note by M. Brioschi, on the equation of the fifth degree, was read.—A note was read on the tension of the vapour of mercury at low temperatures, by M. Regnault,

in which he claims to have proved long ago that mercury gives off vapours even below the freezing point of water. Upon this paper M. Boussingault made some remarks.—M. P. A. Favre presented a paper "On the Electrical Conductivity of Liquids without Electrolysis," in which he gives the details of certain experiments which seem to show that liquids have a conductivity of their own.—M. S. Meunier read a note on the co-existence of two lithological types in the same fall of meteorites. The author stated that the specimens in the Museum at Paris, from the falls of Sigena in Spain, on November 17, 1773, and of Trenzano in Italy on November 12, 1856, each includes two forms of rock, one, the Indian meteoric stone, described by Maskelyne under the name of *basalte*, the other identical with *pamillite*. He remarked upon the singularity of this phenomenon, which, he thinks, indicates that the stones which fell at Trenzano and Sigena were derived from the same deposits, and that *basalte* and *pamillite* have been stratigraphically related.—M. W. de Fonville presented an explanation by means of the theory of fringes of the appearance of luminous halos observed during balloon ascents.—M. Berthelot communicated a further series of thermo-chemical investigations upon the state of bodies in solutions, in which he discussed his researches upon the double decomposition of certain metallic salts.—A note was read on an apparatus for measuring the temperature of alterations and detonations of explosive compounds by MM. L. Leygue and Champion. This apparatus consists of a bar of metal to be heated at one end, upon various parts of which the explosive compounds may be placed.—M. F. Pisani communicated an analysis of the ambygonite (*montebrasite*) of Montebras, showing that the only difference between this mineral and the ambygonite of Arnsdorf consists in its containing a little less soda.—M. A. Trécul read an important memoir on the origin of the lactic and alcoholic yeasts, upon which M. Pasteur made some remarks.—M. H. Sainte-Claire Deville presented a note by M. F. Cailliet on the origin of the carbon fixed by plants containing chlorophyll, which he regards as wholly derived from the carbonic acid of the atmosphere; and M. Bédard referred to memoirs presented by him in 1858 on the influence of violet light upon vital phenomena.

BOOKS RECEIVED

ENGLISH.—Researches of the Calculus of Variations: I. Todhunter (Macmillan and Co.).—Volcanoes, the Characters of their Phenomena: J. P. Seelye (Longmans).—A Vision of Creation, a Poem: C. Collingwood (Longmans).—Hymns for Modern Man: H. Noyes (Longmans).

FOREIGN.—Principes de Biologie appliqués à la Médecine: Dr. Ch. Girard (Baillière et fils).

THURSDAY, JANUARY 11, 1872

THE UNITED STATES DEPARTMENT OF AGRICULTURE*

THE absence of a Department of Agriculture from the complicated scheme of British Government offices leads us to inquire whether it is possible for such a Department in the United States to publish annually eleven or twelve hundred pages of matter useful to the agricultural community, and whether those publications have any considerable circulation in the country.

The question of circulation is abundantly answered by a resolution of the House of Representatives passed on July 14, 1870 (the Senate concurring), which enacted, "That there be printed of the Annual Report of the Commissioner of Agriculture for 1869 *two hundred and twenty-five thousand extra copies*, one hundred and eighty thousand of which shall be for the use of the House, twenty thousand for the use of the Senate, and twenty-five thousand for distribution by the Commissioner of Agriculture." These figures are so startling in their magnitude that they seem to prove too much, until we recollect that the United States of America extend over an area proportionately enormous, including every gradation of climate, from the sub-tropical to the sub-arctic, and every variety of culture, from the cotton and rice of the south to the corn and roots of the north.

That these publications contain matter useful to the agricultural community will be readily admitted after even a cursory examination of either of the volumes; and a careful study of the official reports will lead many people to ask why we in England are not similarly favoured. The United States' Department of Agriculture fulfils two functions. It is primarily a Department of Administration, but it is also charged to acquire information concerning agriculture by means of books and correspondence, by practical and scientific experiments, by the collection of statistics, and by any other appropriate means. The papers in its annual volume include well-considered reports by all the chief officers of the Department, including, besides the Commissioner himself, the statistician, the chemist, the entomologist, the superintendent of the garden and grounds, the botanist, the editor, and others. The papers beyond these official documents consist, for instance, of Reports on Agricultural Education in Europe, on the Beet-Sugar Industry in Europe, on the Agricultural Resources of Alaska, on Agricultural Meteorology, &c. There are also papers on special subjects, many of them of the highest scientific value, such as are published in the journals of agricultural and other societies, and which may be regarded as supplementary to the strictly official work of the Department.

With such a sketch of the United States Department of Agriculture before us, it seems worth while, even in the pages of a scientific journal, to compare it with our English institutions. We have no representative of it as a

department of administration; but we have a series of unconnected departments and commissions, which are as fancifully associated and divided as the stars of heaven in the time-honoured system of constellations. The Privy Council, for instance, takes cognizance of science and art, the education of children, and the diseases of animals. But why it should be the duty of the same high official to protect our flocks and herds from scab, cattle-plague, and other contagious diseases, and at the same time to educate our children, we cannot understand. Is the Vice-President of the Privy Council an *ex officio* Admirable Crichton, or is there some mysterious connection between the three R's and pleuro-pneumonia? Another of our agricultural anachronisms is the Copyhold, Tithe, and Enclosure Commission, which is the State authority on drainage and cottages, as well as the national land surveyor, valuer, and actuary. The Statistical Department of the Board of Trade is entitled to great praise for the manner in which it performs its varied work, including, besides a statistical report on the imports and exports of the United Kingdom, a fair statement of the agricultural condition of the country from year to year. Leaving out of the question the new Local Government Board, the Local Government Act Department, the Poor Law Board, and other departments which are more or less connected with the agricultural interest at home, we come to the Board of Customs, on which agriculturists are dependent for the enumeration of our agricultural imports and exports, while the nation looks to it for the collection of the revenue on our claret and cigars.

Neither as a means of disseminating information have we any representative of the United States Department of Agriculture, with its Annual Report, printed at the expense of the State in editions of nearly a quarter of a million. It is true that the Royal Agricultural Society of England, with less than 6,000 members, does more, probably, in its special walk than any other private society in the world; but it is still nothing more than a private society, and it cannot possibly, therefore, cover the whole ground required by the progressive agriculture of the present day. Indeed, it is, by its charter, expressly prohibited from interfering in matters which are questions of either law or politics. Its efforts are therefore confined to "practice" and "science," and it supports a large staff of scientific officers, including a chemist, botanist, veterinary inspector, engineer, and others, absolutely without State aid; it also expends at least 2,000*l.* per annum in testing machinery; gives away 3,000*l.* per annum in prizes for the best animals; promotes experimental investigations; and incurs very serious risk in exposing adulterations or manures and feeding stuffs.

It may, doubtless, be urged that if English farmers can do so much for themselves they require no help. But practically our Government has found out that there are things to be done which only a Government can do. Thus, after the nation had suffered fearful losses by the ravages of cattle-plague, it ordered an investigation of the subject, and—published a blue-book. After the condition of the agricultural labourer, and especially of women and children employed in agriculture, had been stigmatised as a blot on our civilisation, it issued a Royal Commission, and the result of this excessive effort for the advancement of agriculture was—a series of blue

* Report of the Commissioner of Agriculture for the year 1868, 8vo, pp. 671, Washington, 1869. Ditto for 1869, 8vo, pp. 702, Washington, 1870. Monthly Reports of the Department of Agriculture for the year 1868, 8vo, pp. 423, Washington, 1868. Ditto for 1869, 8vo, pp. 410, Washington, 1869. Ditto for 1870, 8vo, pp. 498, Washington, 1871.

books. But who reads blue-books? Farmers cannot perform successfully a feat which almost baffles the best-trained member of Parliament. What they want is a Department of Agriculture which shall improve the laws of the land, as well as investigate obscure subjects, and circulate the official reports in the manner of the United States department, in editions of a quarter of a million. The United States Commissioner not only expounds the laws of the federation on roads, fences, &c.; but he learns, for instance, that the beet sugar industry of Europe, and the system of agricultural education in Germany and other countries, present instructive features to the intelligent agriculturist, and he therefore sends a qualified commissioner to report on each of these subjects. American farmers are thus enlightened on European agriculture sooner and more authoritatively than we, who are separated from the Continent by nothing more than a "streak of silver sea." There are our Colonies also; and we would on their behalf inquire whether an intending emigrant to Canada, New Zealand, Australia, or the Cape, can obtain as much reliable information on their agriculture as the American farmer now possesses about his country's recent purchase, Alaska? It thus seems clear that the United States Department of Agriculture presents features which may be profitably copied by our Executive Government, and others which are equally instructive both to our agriculturists and to our men of science.

AGASSIZ'S SEASIDE STUDIES

Seaside Studies in Natural History. By Elizabeth and Alexander Agassiz. Marine Animals of Massachusetts Bay: Radiates. 2nd ed. (London: Trübner & Co., 1871.)

THIS is a reprint, with a few additions, of the charming work which became so popular in America and in England some five years since on account of its intrinsic merits and the beauty of the illustrations. The book includes descriptions and more or less truthful illustrations of the Actiniae, Madreporaria, Alcyoninae, Acalephæ, Hydroids, Holothurians, Echinoidea, and Asteroidea which may be found in the neighbourhood of Massachusetts Bay. The history of the development of many of the forms is carefully written, and is obviously the result of patient original observation.

In noticing the reproduction of the Actiniae the authors remark that the eggs which hang on to the inner edge of the partitions of the visceral cavity drop off into it during different stages of development. Ordinarily they are passed out through the mouth as Planula-shaped ciliated creatures, which soon become attached to a foreign substance. The base enlarges, and the free extremity falls in to form a concavity, the future gastric and visceral cavity. But sometimes the embryo is provided with tentacles and with its stomachal cavity before it escapes. Lacaze-Duthiers has described a similar state of things in the reproduction of *Corallium rubrum*, and probably the embryonic condition of all the stony corals is that of a free swimming sac which undergoes metamorphosis. These usually sedentary Actiniae are not without nomadic species, and *Arachnactis brachiola* A. Ag. is described as a small floating anemone, very nocturnal in its habits, which swims

with its tentacles and mouth downwards, using the body as a float. This form is not quite symmetrical, and has an evident tendency towards establishing a longitudinal axis. The mouth is out of the centre. Bicidium is noticed as selecting the mouth-folds of the common large red Cyanea as its home. It undergoes retrograde development, and its tentacles are short and stout on account of its parasitic existence.

The only stony coral described is the littoral *Astrangia*, which is probably a descendant of the miocene forms which once flourished on the same area. The tentacles of this coral are covered with wart-shaped masses, crowded with nematocyst lasso cells. Such forms as *Caryophyllia* and *Balanophyllia*, which are so well represented on our coasts and in thirty fathom water, do not appear to have been found by the authors in Massachusetts Bay. Amongst the Acalephæ, *Cyanea*, of course, is well described, and it is observed that so large a portion of its bulk consists of water that one of no less than thirty-four pounds weight being left to dry in the sun for some days, was found to have lost 99 per cent. of its original weight. Writing of the not very attractive appearance of these huge jelly fish, Agassiz observes that "to form an idea of his true appearance, one must meet him as he swims along at midday, rather lazily withal, his huge semi-transparent disc with its flexible lobed margin glittering in the sun and his tentacles floating to a distance of many yards behind him. Encountering one of these huge jelly fishes when out in a rowing boat, we attempted to make a rough measurement of his dimensions upon the spot. He was lying quietly near the surface, and did not seem in the least disturbed by the proceeding, but allowed the oar, eight feet in length, to be laid across the disc, which proved to be seven feet in diameter. Backing the boat slowly along the line of the tentacles, which were floating at their utmost extension behind him, we measured these in the same manner, and found them to be rather more than fourteen times the length of the oar, thus covering a space of some hundred and twelve feet." This huge mass is produced by a hydroid measuring not more than half an inch in length when full grown.

The parasitic early life of *Campanella pachyderma* A. Ag. appears to throw a doubt whether this acaleph passes through the hydroid state or not. Should the eggs develop at once into the medusa in this instance, there is no small significance to be attached to the fact. An anomaly of an opposite character is noticed in the case of *Laomedea amphora* Ag. This campanularian develops medusæ which never separate from the parent hydroid, but wither on its stem after having laid their eggs. The development of these abortive medusæ is not far advanced. This species flourishes in the sewage of Boston. There is a very admirable drawing of *Tubularia Couthoysi* Ag., a tubularian whose medusæ buds are never freed from the stem, and do not develop into full-grown jelly fish, but always remain abortive. These buds cluster like a bunch of grapes under the expanded umbrella-shaped tentacles of the hydroid, which are gracefully supported by a curved stem.

The process of the budding of the medusæ of *Hybocodon*, where small jelly fish similar to the original grow by gemmation from a large tentacle, is well described, and the hydroid stage and general want of symmetry in the

medusa also. Then the budding from the proboscis of *Dysmorphosa fulgurans* A. Ag. is noticed, and the nomadic or free-floating hydroid *Nanomia* also. Synapta, amongst the Holothurians, is noticed on account of its curious sand-ring clothing. "They live in very coarse mud, but they surround themselves with a thin envelope of fine sand, which they form by selecting the smaller particles with their tentacles, and making a ring around their anterior extremity. This ring they then push down along the length of the body, and continue the process, adding ring after ring, till they have entirely encircled themselves with a sand tube. They move the rings down partly by means of contractions of the body, but also by the aid of innumerable appendages over the whole surface. To the naked eye these appendages appear like little specks on the skin; but under the microscope they are seen to be little warts projecting from the surface, each one containing a little anchor with the arms turned upward. Around the mouth the warts are larger, but do not contain any anchors." "By means of these appendages, though aided also by the contractions of the body, the Synapta move through the mud, and collect around themselves the sand tube in which they are encased." They gorge themselves with mud and sand for the sake of the nutritious substances they may contain. The office of the pedicellariæ of the Sea Urchin is well described, as follows:—"If we watch the Sea Urchin after he has been feeding, we shall learn at least one of the offices which this singular organ performs in the general economy of the animal. That part of his food which he ejects passes out at an opening on the summit of the body, in the small area where all the zones converge. The rejected particle is received on one of these little forks, which closes upon it like a forceps, and it is passed on from one to the other down the side of the body till it is dropped off into the water. Nothing is more curious and entertaining than to watch the neatness and accuracy with which this process is performed. One may see the rejected bits of food passing rapidly along the lines upon which these pedicellariæ occur in greatest number, as if they were so many little roads for the carrying away of the refuse matters; nor do the forks cease from their labour till the surface of the animal is completely clean and free from any foreign substance." Some higher animals might take a profitable lesson from the Urchin. The Crinoids are passed by rather briefly. The existence of Comatulæ from Greenland to South Carolina is mentioned, but the authors do not appear to have devoted special attention to them. A very excellent notice of the embryology of the Echinodermata precedes the last chapter, which consists of a brief *résumé* of the distribution of life in the ocean. The book might be taken as a model by many European naturalists who write popular works, for there is a vast amount of philosophy in it. The authors have not contented themselves with serving up a number of "wonders" for the public bewilderment; nor have they simply given us a series of descriptions of forms, as is the practice especially amongst those who trade upon butterflies and beetles; but they have taken a vast amount of trouble in explaining the development and embryology of the Invertebrata which have come under their notice. In fact, they have given a reasonable amount of bread with their "sack."

EARNSHAW'S DIFFERENTIAL EQUATIONS

Partial Differential Equations. An Essay towards an entirely new Method of Integrating them. By S. Earnshaw, M.A. (Macmillan and Co., 1871.)

THE present work, as its title indicates, contains a detailed explanation of a new method of integrating Partial Differential Equations; it is in no sense a textbook or introduction to the subject. The author's object is not to collect and describe the known methods, but to develop a new one. The principle of the method is easily explained and understood. The independent variables in the given differential equation being $t, x, y, z, \dots$, we can transform it so that the new independent variables are $t, \xi, \eta, \zeta, \dots$, by equations of the form $D_t u = d_t u + d_{\xi} u \cdot D_t \xi + \dots$; but the practical application of the method consists in comparing the original equation with the equation last written, and thus determining relations from which, by the elimination of $\xi, \eta, \zeta, \dots$, the integral of the original differential equation is found. The quantities $t, \xi, \eta, \zeta, \dots$, with the exception of the one with regard to which the differentiation is being performed, are treated as constants, and are here called *quasi-constants* (semi-constants we should have preferred). Mr. Earnshaw, as is apparent from the equation of transformation quoted above, adopts d when the differentiation is with regard to the old variables, and D when with regard to the new; the suffix notation for differential coefficients is also made use of. For this latter departure from custom the author in the preface offers an apology, and states that he has been warned that it "will form a serious hindrance to the acceptableness of the present work." This fear we think is groundless; the notation is not inconvenient in such investigations as the present, as it somewhat simplifies the appearance of the equations without rendering the analysis more difficult to follow.

In the first few chapters the method is applied to the integration of numerous equations of the first and second orders, and throughout the book the applications to particular cases are so numerous that whole chapters consist entirely of "examples worked out." This excessive number of examples is a drawback, as many of them (for instance, all in Chapter V., which treats of linear equations of the second order with constant coefficients) can be more simply and perfectly discussed by Boole's symbolic and other methods. The reader is also left in doubt as to how far the examples have been chosen so as to suit the method of solution here adopted. In the development of a new principle it is always a matter of great importance to point out the cases in which it enables us to obtain results previously beyond our reach, and also the cases in which the previous methods are preferable. This Mr. Earnshaw does not appear to have done; he has integrated a great number of equations, many of which, however, are capable of solution by well-known methods in as straightforward a way as ordinary quadratics in algebra. It is, for such reasons as these, generally desirable that original mathematical investigations should appear first in the memoirs of a Society or other recognised organ, where the new matter is distinctly stated, rather than in the form of a book where there is nothing to check the temptation to overburden the explanation with examples. Mr. Earnshaw claims to have for the first time integrated in

finite terms several most important partial differential equations of the second order, including the equation of continuity in a homogeneous incompressible fluid; and the chapters in which these equations are discussed are by far the most important and interesting in the work. Mr. Earnshaw is already known for his able treatment of the equation for the motion of a sound wave in the *Philosophical Transactions* for 1860, and no one can doubt the importance of the subjects suggested for consideration by this and other equations. The question is discussed whether there must necessarily exist an integral of every partial differential equation that can be proposed, and on this part of the subject we wish the author had extended his remarks. The real question considered seems however rather to be the possibility of the existence of a continuous function expressible in finite terms as an integral. With regard to the considerations having reference to certain physical problems, we should not expect to learn very much from the discussion of such questions, as the differential equation might admit of a solution incapable of satisfying the physical conditions.

We must notice one singular error made by Mr. Earnshaw. He concludes that the well-known partial differential equation of the second order of surfaces having their principal radii of curvature equal and of opposite signs at all points, admits of no integral, because the form of a surface possessing this property would be such as could not exist; but it is well known that the surface formed by the revolution of a catenary round its directrix does possess the property in question, and it is easy to see that this arises simply from the fact that the normal and radius of curvature in the catenary are equal and of opposite signs; the form of the surface is quite easy to conceive. A particular integral of the equation obtained by Poisson's method is also given in Boole's *Differential Equations*, chapter xv. Even admitting Mr. Earnshaw's reasoning, it would only establish the non-existence of a real surface possessing the required property. The integrals of the equation of continuity in three dimensions, and of one or two other equally important equations, we do not remember to have seen before, and they are perhaps the most general finite solutions the equations admit of. Of the value and power of the method it is impossible to speak at present; but we heartily commend Mr. Earnshaw's book to the reader as one containing much matter of great interest systematically and clearly developed and treated by a novel method. It is remarkable that the subject of partial differential equations has not attracted more attention than it has in recent years, as an advance in this quarter is more immediately felt in physics than an advance in any other pure mathematical subject. The present work will help to bring the matter prominently forward; and as the analysis is nowhere of a very difficult nature, it will probably come under the notice of many readers not accustomed to study mathematical memoirs on their appearance.

If the work had been intended to be a Treatise on the subject, we should have had good reason to object to the total omission of all reference to the usual methods, but the title and preface explain that this was not contemplated; it is one of the few English books containing original mathematics.

J. W. L. G.

OUR BOOK SHELF

Three and Four Place Tables of Logarithmic and Trigonometric Functions. By James Mills Peirce. 16 pp. (Boston : Ginn Brothers, 1871.)

PERHAPS the best way of treating this work, which does not contain a single word of explanation, will be to give a summary of the tables contained in it. First we have proportional parts of all numbers up to 100; then on one page three-place logarithms of numbers and of the six trigonometric functions, natural and logarithmic. On pages 4 and 5 we find four-place logarithms of numbers, then logarithms of sums and differences (Gaussian logarithms) also to four places, then follow tables of logarithmic trigonometric functions, inverse trigonometric functions (a new table, to which attention is specially invited, for finding angles from the logarithms of their trigonometric functions), traverse table, the correction of the middle latitude (in an improved form), and meridional parts.

In a prospectus issued by the publishers, it is stated as a result of experiment that it has been found that the times occupied, in regular computation, in doing one piece of work by tables of 4, 5, 6, and 7 places, are proportional to the numbers 1, 2, 3, and 4; hence it is that the author has drawn up the majority of the tables under review to 4 places as sufficient for ensuring the degree of accuracy usually required in computations of common surveying, engineering, &c.

The type employed is very clear, the arrangement of the work is good, and the printer's part has been well done; the book requires only a few words of elucidatory matter. There is on the last page a useful Table of Constants with their logarithms, here we observe a few symbols which are new to us, and which are presented to our notice on the Title-page.

After all the value of such a work consists in its accuracy, and that can only be tested by practice, "the greatest pains have been taken both in preparing and printing to secure perfect accuracy." We commend the work to the notice of such as agree with old Burton (*Anatomy of Melancholy*, pt. II., sec. 2), "What so pleasing can there be . . . if a man be more mathematically given (as) to calculate or peruse Napier's logarithms, or those tables of artificial sines and tangents, not long since set out by . . . Edmund Gunter, which will perform that by addition and subtraction only, which heretofore Regiomontanus' tables did by multiplication and division." But then the same quaint writer advises those who are melancholy to square a circle; does it follow that all circle-squarers are melancholy? R. T.

The Latus of the Winds prevailing in Western Europe. By W. Clement Ley. Part I. (Stanford, 1872.)

EVEN when we differ from an author's conclusions, the work of one who shows himself an honest and capable inquirer has a just claim to our attention. Mr. Ley evidently writes from practical knowledge of his subject, and his assiduity in collecting and charting observations must have entailed on him an amount of labour which only those who have been engaged in similar work can thoroughly understand. Unfortunately, as it appears to us, he has confined his investigations almost entirely to the limits set forth on his title-page; and the winds of Western Europe, though highly suggestive and subject to more exact observation than any others except those of the United States, are by no means to be taken as representative. Mr. Ley has taken them as such, and has thus laid down a series of general propositions, which may be briefly summed up in one—that revolving storms are caused by the barometric depression consequent on heavy rain over a large area. He brings forward some curious home instances in illustration of this; but looking farther afield, on the slopes of the Himalayas—to mention only one locality—a much heavier and longer continued pre-

precipitation than any he has instanced takes place every summer, and does probably cause a very great depression of the barometer, but certainly does not give rise to any winds such as he has described. On the hills of Khasia, again, where the unparalleled rainfall is as much as from 30 to 40 inches a day for days together, and puts the paltry $\frac{1}{2}$ or $\frac{3}{4}$ of an inch a day of Mr. Ley's examples almost beyond the pale of comparison, no such storms are generated. In the same way, the explanation of the eastward direction which these barometric depressions take in our latitudes, which differs only in its greater detail from that given by Prof. Mohn in the "Storm Atlas," is applicable only to temperate latitudes; the westward advance of tropical cyclones cannot be referred to it; and it seems to us improbable in the extreme that the course of a storm is regulated by one law in one part of the world, and by a totally distinct law in another. Besides this, in the detailed application of the law which he deduces for Western Europe, the author appears to fall into the mistake of attributing the rainfall of mountain districts to the mere contact of the moist air with the cold mountain slope; that this is not the case—that it is due rather to the hoist into the upper regions which the air receives on impinging against the slope—is curiously shown by the fact that, when the hills are not high, most rain falls on the lee side. One familiar instance of this will illustrate our meaning. The gauge which in all England shows the greatest rainfall is at Stockley Bridge, just above Seathwaite; it is distinctly under the lee of the ridge which joins Great Gable to Great End, and separates Wastdale from Borrowdale. The mist, blown in from seaward, fills Wastdale, and is lifted up the slope of this ridge (Stye Head Pass). Crossing over out of Wastdale, the mist curling up the hill is frequently so thick that the path cannot be seen 10 feet in advance; but immediately on reaching Stye Head Tarn the mist vanishes, to fall as rain over Seathwaite. But altogether, though we admit neither the author's premises nor his conclusions, his work is none the less highly interesting. It does not contain much that is new, but it discusses and illustrates the theories of Mohn and Buchan in greater detail than has yet been attempted. We would, however, decidedly object to the *ex cathedra* tone which is occasionally adopted. In empirical science very little is "obvious," and perhaps nothing is a "truism;" certainly the influence attributed to the earth's rotation is neither one nor the other, for it is denied, disputed, and doubted by very many capable meteorologists.

J. K. L.

The Young Collector's Handy-book of Botany. By the Rev. H. P. Dunster. (London: L. Reeve and Co., 1871.)

WE opened this little book with pleasure, hoping to find in it an addition to the too few popular manuals of botany, and the pleasure was increased by recognising at the end some familiar and excellent illustrations. Great therefore was our disappointment when we found that instead of "assisting the student in the beginning of his work by setting him forward on a right road," as is stated in the Preface to be its object, it would be far more likely to mislead him. Botany seems to be peculiarly unfortunate, in that every one who is fond of flowers thinks himself capable of writing a handbook, without himself possessing any accurate scientific knowledge of his subject. Some of the definitions given in this book are so bad that we should have been surprised to find them in the answers to the examination papers of the botanical classes in any of the great schools where natural science is now taught. Take four examples:—"Albumen: a gummy substance surrounding certain seeds;" "Embryo: the leaf in an immature state;" "Matrix: that upon which any other thing grows;" "Petals: leaves while in the corolla." After this we are somewhat prepared to hear that the corolla "is made up of petals which, when expanded, are the flower-leaves, and of the stamen and pistils;" and that "county collections (of ferns) are valuable as illustrations

of the *fauna* of particular parts." We are utterly unable to see the object gained by the publication of this book, when beginners already have such admirable manuals as Oliver's "Lessons in Elementary Botany," Lindley's "School Botany," and Cooke's "Manual of Structural Botany," neither of which, by the way, is mentioned by Mr. Dunster in the list of books recommended to the learner. Especially are we unable to understand how the names of respectable publishers, who have issued many admirable works on natural history, come to be appended to a book of this character. As we see that it is intended to be the first of a series of Handy-books upon "the popular and recreative sciences," we would recommend the publishers to submit the manuscript of the remainder of the series to a competent judge before publication. A. W. B.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Ocean Currents

LEAVING out of account a few small inland seas, the globe may be said to have but one sea, as well as but one atmosphere. We have, however, accustomed ourselves to speak of parts, or geographical divisions, of the one great ocean, such as the Atlantic and the Pacific, as if they were so many separate oceans. We have become accustomed, also, to regard the currents of the ocean as separate, and independent of one another; and this idea has, no doubt, to a considerable extent, militated against the acceptance of the theory, that the currents are caused by the winds, and not by difference of specific gravity, for it leads to the conclusion that currents in a sea must flow in the direction of the prevailing winds blowing over that sea.

The true way of viewing the matter, as I hope to be able to show in my next letter on the cause of Ocean Currents, is to regard the various currents merely as members of one grand system of circulation, produced, not by the trade winds alone, as some suppose, but by the combined action of all the prevailing winds of the globe, regarded also as one system of circulation.

If the winds be the impelling cause of currents, the *direction* of the currents will depend upon two circumstances, viz. (1) the direction of the prevailing winds of the globe; and (2) the conformation of sea and land. It follows, therefore, that as a current in any given sea is but a member of a general system of circulation, its direction is determined, not alone by the prevailing winds blowing over the sea in question, but by the general system of prevailing winds. It may, consequently, sometimes happen that the general system of winds may produce a current directly opposite to the prevailing wind blowing over the current.

Taking into account the effects resulting from the conformation of sea and land, the system of ocean currents is found to agree exactly with the system of the winds. I trust to be able to show that all the principal currents of the globe, the Gibraltar current not excepted, are moving in the exact direction in which they ought to move—assuming the winds to be the sole impelling cause. Given the system of winds and the conformation of sea and land, the direction of all the currents of the ocean, or more properly the system of oceanic circulation, can be determined *a priori*. Or given the system of the ocean currents, together with the conformation of sea and land, and the direction of the prevailing winds can also be determined *a priori*. Or, thirdly, given the system of winds and the system of currents, and the conformation of sea and land may be, at least, roughly determined. For example, it can be shown by this means that the Antarctic regions are probably occupied by a continent, and not by a number of separate islands, nor by a sea.

The influence of the rotation of the earth on ocean currents has certainly been greatly over-estimated. Rotation, as is well known, exercises no influence in generating motion in any body placed on the earth's surface; but if this body be already in motion, no matter in what direction the motion may be, rotation will deflect it to the right on the northern hemisphere, and to the left on the southern hemisphere, as has been shown by Mr. Ferrel. But it must be borne in mind that the deflecting power of rotation depends wholly on the rate at

which the body is moving. If difference of specific gravity be regarded as the impelling cause of any current, the deflecting power of rotation will certainly be infinitesimal.

Difference of specific gravity, resulting from difference of temperature between the ocean in equatorial and polar regions, might, if sufficiently great, produce some such interchange of equatorial and polar water as Dr. Carpenter supposes; but surely the difference of temperature between the equator and the poles could not produce currents like the equatorial current and Gulf Stream in a wide expanse of water. Such a general difference of temperature might tend to produce a general motion of the ocean; but it is inconceivable that it should produce motion in particular parts of the ocean, as Maury, Colding, and others, conclude.

But I think it is by no means difficult to prove that the circulation of the waters of the ocean cannot be due to the difference of temperature between the equatorial and polar regions. And Dr. Carpenter must be mistaken in supposing that it requires great mathematical skill to determine the value of the forces to which he attributes the circulation of the ocean. The whole subject, when properly viewed, resolves itself into a mechanical problem of such extreme simplicity as not to require for its solution the aid of any mathematics whatever in the ordinary sense of the term. Taking Dr. Carpenter's own data as to the difference of temperature between the waters at the equator and the poles, and also his estimate of the rate at which the temperature of the equatorial waters decreases from the surface downwards, I have, in my paper in the *Philosophical Magazine* for October last, proved that the amount of force which gravity exerts on, say, a pound of water, tending to make it move from the equator to the poles supposing the pound of water to be placed under the most favourable circumstances possible, is only $\frac{1}{100}$ of a grain.

I have shown also that the greatest amount of work that gravity can perform in impelling the waters from the equator to the poles as a surface current, and back from the poles to the equator as an under current (assuming that the waters would actually move under an impulse so infinitesimal) is only nine foot-pounds per pound of water. And in regard to the Gibraltar current, the amount of work which gravity can perform does not exceed one foot-pound per pound.

If these results be anything like correct, and it be admitted that a force so small is insufficient to produce the necessary motion, then it is needless to expect that any future observations in reference to currents of the ocean will in the least degree aid Dr. Carpenter's theory; for, supposing it were found that the waters of the ocean do circulate in some such manner as he concludes—a supposition very improbable—still we should be obliged to refer the motion of the water to some other cause than that of differences of temperature. JAMES CROLL

Edinburgh, Dec. 22, 1871

"Nature Worship"

In a spirited article under this title in the last number of the *Medical Times and Gazette*, we are accused of "the most dismal want of appreciation of the true scope of the medical art and science." This is hard! The ground for it is to be found in the following sentences in the short notice of the Brown Institution in *NATURE* of Dec. 21:—

"The true physician fears to meddle with the processes of which he is the attentive and anxious spectator. Although the more ignorant members of the medical craft—the so-called 'practical' men—may sometimes, with the best intentions, experiment on their patients with harmful drugs, such experimentation is repudiated by the man of Science."

If objection had been taken by our guarded suggestion that it may happen that practitioners may sometimes use powerful agents by way of remedies without any adequate knowledge of their property, we should not have been surprised, and would have been very willing to apologise had we been assured that the insinuation was unfounded. What our critic finds fault with, however, is the second part of the sentence, viz., our assertion that such experimentation on human beings with harmful drugs is objectionable. If experiments had never been made on human beings, he argues, we should not have learnt to know some of our most useful and valuable drugs. This may be so; but even if it is, it perhaps scarcely affords a sufficient justification for a continuance of the practice.

In another part of the article we are accused of "unconsciously reproducing the superstitious and false philosophy of

2,000 years back," and we are distinguished by the epithet "Nature worshippers." Let us quote the superstitious sentence which has laid us open to so unexpected an imputation:

"The pathologist at the bedside is not in the position of an experimenter, but only in that of a student, who stands by at a greater or less distance; while another over which he has no control performs experiments in his presence without deigning to explain to him their nature or purpose."

By these words we are supposed to imply that while nature works we worship. Does the student who stands by while the professor performs an experiment in his presence, the nature of which he very imperfectly understands, ready to help if need be, but fearing to meddle or even ask a question lest he spoil the wished-for result, worship his teacher? Or is it the mere speaking of Nature as a teacher at all that is superstitious and unphilosophical?

The truth is, that our contemporary has obviously found the sentences quoted from our article a convenient text for a telling homily on a subject with which our remarks had nothing whatever to do. Our object was to point out that for the purposes of pathological investigation, and for trying the action of unknown remedies, a fellow mortal stretched on a sick bed is not a fit subject; that it is better to use dogs, cats, and rabbits. His aim, on the other hand, is to impress upon his readers the important practical lesson, that the doctor when called to see a patient must not stand by inactive, but use every means at his disposal for the relief of suffering and the prolongation of life. If he had found that he could add force to the admonition by clothing it in figurative language, and had said that the physician should grapple with the disease as with a fiend, it would not have occurred to us to call him a "devil worshipper."

THE WRITER OF THE NOTICE

Prof. Helmholtz and Prof. Jevons

JEALOUS of any and every restriction to that full liberty of scientific thought which cannot be over-advocated, we have recently gone so far as to deny the necessary and universal validity of the old axioms or "self-evident principles," not only in geometry, but in logic. Now I would submit that, if without some elementary or initial certainties all scientific thought is impossible, we must either retract these denials altogether, or so far limit them as to leave the logical certainties intact. But can we do the latter while geometrical axioms are in dispute? Towards answering this question, I propose to consider the hypothesis advanced by Prof. Helmholtz, to be found in *NATURE*, No. 103, October 19, and ably commented on by Prof. Jevons.

In order to show how geometrical axioms, with conclusions based thereon, may not be necessarily or universally true, Prof. Helmholtz tells us "to imagine the existence of creatures whose bodies should have no thickness, and who should live in the mere superficies of an empty globe," and then, as a consequence, to admit that, "while, with us, the three angles of a rectilinear triangle are exactly equal to two right angles, with them, the angles of a triangle would always, more or less, exceed two right angles." I propose to show that this position, so far as it affects the question, contains a logical uncertainty and unsoundness, which, if admitted, would vitiate all reasonings whatsoever.

We should premise that the "imagined creatures" are supposed to be "in possession of human powers of intellect," however their external conditions differ from ours. This assumed (and conceded), Prof. Helmholtz has to prove that the assumed difference of the external conditions will necessitate the intellectual difference assigned in his hypothesis; but he cannot assume this also without begging the whole question.

Let us first ask, what here is the import of the expression, "with them, the angles of a triangle would always, more or less, exceed two right angles?" To take the term "exceed," do the supposed beings detect the excess, or not? If they do, they find these three angles exceed two of our right angles, and they are acquainted with our right angles, and are consequently capable of conceiving four such rectilinear angles, and, thence, a rectilinear triangle with all its angles together equal to two right angles; and thus the entire supposition is unproductive. If we assert now that they do not detect the excess because they cannot, under their new conditions, conceive a rectilinear figure, we are simply begging the question we proposed to institute, viz., whether we derive our geometrical notions through our conditions, or whether these notions are intuitive? And, lastly, if we say that the beings in question take the spherical angles they have for rectilinear angles, and their four equal angles about a

point for four right angles, *i.e.*, that they have our notion, but missapply it; then it follows that they have our conclusion, that the angles of a triangle together equal two right angles; and their missapplying does not avail anything, seeing that the geometrical conclusion (the universality of which is here disputed) does not propose to deal with facts, but with suppositions only. The supposed rectilinear figures of these beings are (though wanting all physical counterparts) the very figures of Euclid.

Now, first, the fallacy lies in what the late Professor John Grote called the "pseudo-psychology," the confusion of thought and thing, of the psychical and the physical. For the question is here of geometry, the science which regards (say) all the supposed or postulated rectilinear angles about a point as equal to four right angles: the question is not of the physical science which discovers "more or less" exactly what angular or other qualities may belong to any physical object; and so true is this, that geometry is not conversant with right and left hand, nor with above and below. And, secondly, the fallacy is concealed by an ambiguous use of terms in the statement, "with them, the angles of a triangle would always, more or less, exceed two right angles." The "with them" may mean with them in imagination, or with them in fact; and, but for this ambiguity, the fallacy must have exposed itself; for, first, it is obvious that two angles which they imagined right ones would, in their imagination, equal, and not be "exceeded by" the angles of a triangle they imagined rectilinear; we could not have said otherwise than this, with the case clearly stated. And, secondly, we could never have said (distinctly) that the physical fact being one way or another, could affect the universality of a geometrical position which does not affirm anything of physical facts; but we should have perceived that we were only combating a statement that the angles of a physical triangle supposed to be, though not really, rectilinear, are together really equal to two right angles; a statement obviously not true, and as obviously not geometrical.

In mathematical argument, anything I should bring in aid of Prof. Jevons's able comments would be equally presumptuous and useless; and it is only because I feel that his reasonings are not quite so unassailable on the psychological side that I venture any additional evidence. Prof. Jevons asks (I think needlessly), "Could the dwellers in a spherical world appreciate the truth of the 32nd proposition of Euclid's first book? I feel sure that, if in possession of human powers of intellect, they could. In large angles the proposition would altogether fail to be verified; but they could hardly help perceiving that, as smaller and smaller angles were examined, the spherical excess of the angles decreased, so that the nature of a rectilinear triangle would present itself to them under the form of a limit." Now the terms "spherical excess" here mean the quantum by which all the angles of their triangle would, to the knowledge of these beings, exceed two *bonâ fide* right angles. They therefore know already (by Prof. Jevons's supposition) what a rectilinear angle is, and, hence, what a rectilinear triangle is with all its geometrical properties (as above shown), for it is admitted that we require no objective experience beyond that of a rectilinear angle in order to deduce said properties, and these beings, having our intellectual powers and our data, can deduce the same. I would only suggest here that, after this, to suppose any experimental evidence necessary to "verify" the proposition is very much like conceding the hypothesis that geometrical conclusions are not independent of experience.

Another point not directly met by Prof. Jevons is ingenious, but amounts to the assertion that, if we could not actually *draw* a straight line, we should not be able to define it as "the shortest distance between two points;" for these imagined beings, who cannot possess a physical straight line, will have "an infinite number of shortest lines between any two diametrically opposite points in their sphere." An argument, interesting only so far as it illustrates to what lengths of ingenuity a sophism may be carried; for have we not to prove that our geometrical conception or definition depends upon our physical experience, and are we not here advancing for proof, that beings without this experience cannot have the geometrical conception, and that they cannot have it because—we cannot have it? If anything could convince us of the inherent impotence of these *experimental hypotheses*, it should be this inevitable appearance of the "circle" just when proof is called for. And again, "shortest distance" here has two senses. First it means the shortest path available to the imagined beings, and then (in order to invalidate the definition of a straight line) it means the shortest path conceivable.

If this case it appears then (as I proposed to show) that, while

the geometrical certainties have been questioned, the logical code has been violated, and all logical certainty confounded by an ambiguous use of terms. I have here attempted no demonstration of the opposite theory; but I think if the eminent supporters of the hypothesis just examined would be content to affirm roundly that all our notions, conclusions, and beliefs are mere resultants of intellectual action *plus* given experience, and to forbear any hypothetical deductions till this thesis is made good, they would find that the essence of the question is distinctly psychological, and that any experiments with hypothetical physics are so many attempts to get out of a complex thing that which is simply not in it.

J. L. TUPPER

Meteorological Phenomena

ON the 10th of November, a little after 4 P.M., the sun was behind a bank of thick stratus clouds, on the upper edge of which, attached to it, about 10° above the sun's position, and 15° to 20° to the north of it, I, with two other persons, observed a small irregularly-shaped cloud, about 2° in apparent diameter, which exhibited the colours of the least refrangible portion of the spectrum, commencing with the red on the south end nearest the sun, succeeded by orange, yellow, and pale greenish yellow, fading into white on the north edge, the rays being perpendicular. This appearance continued for about five minutes or upwards while we viewed it, and then faded away. Though the phenomenon appears simple, the light cloud merely refracting the sun's rays, it is not evident why the complementary colours of the more refrangible portion of the spectrum should not have been visible; and, as far as I am aware, a similar appearance has not been recorded before. G. F. D.

IN NATURE of August 31 there is a note headed, "A Rare Phenomenon," from Magdeburg. Your correspondent, I think, evidently refers to what in India, or at any rate in Ceylon, is called "Buddhi's Rays," an appearance in the sky very commonly observed here, and for which I have never heard any scientific explanation attempted. I regret to say that hitherto I have never taken any exact notes of the position of these rays. They generally occur, I think, when the sun is low, sometimes in the west at sunset, but also occasionally in the east. The appearance presented is that of alternate broad streaks of rose colour and blue radiating from one point on the horizon, and extending, I should say, for about thirty or forty degrees. I will, whenever I see them in future, take exact notes of their position, &c. At present I can only say that I certainly think that dust in the atmosphere can take no part in their production.

Colombo, October 1871

BOYD MOSS

Cranngos in the South of Scotland

IT may interest some readers of NATURE to learn that a considerable number of cranngos, various articles of the New Stone Period, and some "kitchen-middens" have been discovered in connection with the small lochs which stud the surface of Wigtonshire and Dumfriesshire. Dowalton Loch, Machermore Loch, and the lochs which surround Castle Kennedy in Wigtonshire, have been examined within the last few years, and have disclosed ancient lake-dwellings. The Black Loch of Sanquhar and Lochmaben Loch in Dumfriesshire contain platforms of wood and stone. In some cases canoes and causeways connecting the artificial islands with the adjacent shores have been traced. Sir William Jardine, in his presidential address to the Dumfries Natural History Society, 1864-5, gives an interesting account of the cranngos discovered at Sanquhar Black Loch; and recently the Rev. Geo. Wilson, Glenclue, read a detailed description of the cranngos in his vicinity to the Scottish Antiquarian Society.

J. SHAW

Freshwater Lakes without Outlet

IN your notice of Morelet's "Central America" (NATURE, December 28, 1871) you speak of the water of the lake of Peten as fresh, though without an outlet. This is uncommon, but not unexampled. The lake of Arauca in Venezuela, described by Humboldt, is of this kind, and so are the lakes near Damascus, into which the Abana and Parphra respectively discharge. The best account of these latter is, I believe, in Mr. Macgregor's work, "The Red Sea on the Jordan."

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Jan. 1

Pupa of *Papilio Machaon*

WHILST working at the colour patterns of Insects in November 1867, I very carefully dissected off a portion, about one-eighth of an inch square, of the hard integument from the side of a pupa of *P. Machaon*, near the anterior extremity. The portion of the interior thus displayed was filled with a clear colourless fluid, in which was floating a delicate membrane, to which were attached several tubes, trachea, formed by a spiral fibre. In the fluid were floating many roundish grains. Another pupa of the same brood was examined January 15, 1868, and another on April 15. The floating grains were now evidently made up of ganglia of the spiral fibre of the trachea, and were connected with the tube by long pedicels of the same kind of fibre. On May 20 the tubes had enlarged to such an extent that they were almost contiguous, and were covered with minute granules, apparently incipient scales; in fact, a few small but well-formed scales appeared on one portion. The specimen examined in November was laid in cotton; a perfect cicatrice was formed, and the butterfly in excellent condition appeared at the usual time.

Rainhill, December 23, 1871

HENRY H. HIGGINS

Lunar Calendars

In reply to "Myops" in NATURE, No. 111, p. 123, the English New Moon of the Jews is really the Month-Head (*Caput mensis*), formed from an artificial system. The true mean conjunction derived from the 19-year cycle is called the Molad or Moon-Birth, and generally differs from the festival-day.

Said artificial system consists in combining AZ, BY, CX, &c., as follows:—

1st Day of Passover has Black Fast (9th Ab) on same week day.	
2nd " " " 1st of Pentecost. do.	
3rd " " " 1st of New Year (Tishri). do.	
4th " " " Last of Tabernacles—Rejoicing of Law. do.	
5th " " " White Fast (Atonegment Day). do.	
6th " " " Preceding Purim (Esther's Feast). do.	

This actual Jewish Calendar depends on the Moveable Feasts, 1st Passover never falling on Monday, Wednesday, or Friday.*
39, Howland Street, W., Dec. 15, 1871 S. M. DRACH

Hints to Dredgers

APPEALED to by name—spirits from the vasty deep—I have waited for my elders, also named, to answer Mr. Hennah's queries about dredging, and, failing to see anything more, I venture to trouble you with a few lines, the more so as I felt the want of advice when I was fitting out the *Norna* in 1870. Details would be out of place here; I will only at present give a few hints. And first—to repeat Punch's advice to those about to marry—if about to buy a yacht, DON'T! Begin by hiring one of the tonnage you require, the proper price being 1*l.* 5*s.* per ton per month, including the wages of skipper and crew, but rarely of cook or steward. After your first season buy by all means if you like.

If bound on a long cruise your craft should not be under 80 to 100 tons. But for dredging in the Channel or round our coasts 25 tons and upwards are sufficient; but not on any account under that. A little boat of 25 tons makes up two good berths and two more possible ones, exclusive of the crew's sleeping quarters, and being decked stands a good chance in a gale of wind.

Beware the discomfort of a half-deck and a small boat, remembering that you may unavoidably have to face some nasty breezes which an ordinary yachtsman would run away from. You may, for instance, be caught in a bay offering rich results, and have to thrash out of it.

Hire a man knowing the locality in which you desire to try your fortune.

Take a particular line, say the comparative life on the borders of fresh and salt water junctions, or at spots where the depth suddenly increases. No better locality, with a good pilot, could be picked out to begin with than the Channel Islands.

Especially note the submarine geology. Exactly fix the spots you dredge in by cross bearings. A small prismatic compass is invaluable, both afloat and ashore. Take carefully temperature, current, tidal observations, a multitude of soundings, and keep specimens of all. Fill a private log-book with the most trivial and infantile details. You will afterwards laugh at much you have noted; but it is a great gain, and, unlike partridges, impressions are best fresh.

* For Mahomedan Calendar inquire of a Moslem, or such an authority as Capt. R. J. Burton, the famous Hajji El-Iraki, and Consul to El-Sham.

This is not the occasion to go into matters of outfit. One thing I must name, on no account let any man on board be without a life-belt for his own use.

Any intending dredger writing to me at this club will be cordially answered. A small squadron of yachts working together under a commodore of their own election would partition the labour, and produce a little emulation among the crews. Make a rendezvous every few days, and talk results over.

MARSHALL HALL

New University Club, St. James's Street, S.W., Jan. 6

Anacharis Canadensis (A. Alsinastrum)

I SHOULD esteem it as a favour if you would allow me to ask, through the medium of NATURE, if there be any published account of observations, confirmatory or otherwise, of Mr. Wenham's notes on the free-cell formation which he has described as being carried on at the terminal growing point of *Anacharis*, quoted by Dr. Carpenter in "The Microscope and its Revelations," p. 405, *et seq.* (3rd ed.)

H. POCKLINGTON

FIGHT BETWEEN A COBRA AND A MONGOOSE *

THE snake was a large cobra 4 ft. 10½ in. in length, the most formidable cobra I have seen. He was turned into an enclosed outer room, or verandah, about 20 ft. by 12 ft., and at once coiled himself up, with head erect, about ten or twelve inches from the ground, and began to hiss loudly. The mongoose was a small one of its kind, very tame and quiet, but exceedingly active.

When the mongoose was put into the rectangle, it seemed scarcely to notice the cobra; but the latter, on the contrary, appeared at once to recognise its enemy. It became excited, and no longer seemed to pay any attention to the bystanders, but kept constantly looking at the mongoose. The mongoose began to go round and round the enclosure, occasionally venturing up to the cobra, apparently quite unconcerned.

Some eggs being laid on the ground, it rolled them near the cobra, and began to suck them. Occasionally it left the eggs, and went up to the cobra, within an inch of its neck, as the latter reared up; but when the cobra struck out, the mongoose was away with extraordinary activity.

At length the mongoose began to bite the cobra's tail, and it looked as if the fight would commence in earnest. Neither, however, seemed anxious for close quarters, so the enclosure was narrowed.

The mongoose then began to give the cobra some very severe bites; but the cobra after some fencing forced the mongoose into a corner, and struck it with full strength on the upper part of the hind leg. We were sorry for the mongoose, as but for the enclosure it would have escaped. It was clear that on open ground the cobra could not have bitten it at all; while it was the policy of the mongoose to exhaust the cobra before making a close attack. The bite of the cobra evidently caused the mongoose great pain, for it repeatedly stretched out its leg, and shook it, as if painful, for some minutes. The cobra seemed exhausted by its efforts, and putting down its head, tried hard to escape, and kept itself in a corner. The mongoose then went up to it and drew it out, by snapping at its tail, and when it was out, began to bite its body, while the cobra kept turning round and round, striking desperately at the mongoose, but in vain.

When this had continued for some time, the mongoose came at length right in front of the cobra, and after some dodging and fencing, when the cobra was in the act of striking, or rather, ready to strike out, the mongoose, to the surprise of all, made a sudden spring at the cobra, and bit it in the inside of the upper jaw, about the fang, and instantly jumped back again. Blood flowed in large drops from the mouth of the cobra, and it seemed much

* The following interesting narrative has been obligingly forwarded to us by Prof. Andrews, of Queen's College, Belfast.

weakened. It was easy now to see how the fight would end, as the mongoose became more eager for the struggle. It continued to bite the body of the cobra, going round it as before, and soon came again in front, and bit it a second time in the upper jaw, when more blood flowed. This continued for some time, until at last, the cobra being very weak, the mongoose caught its upper jaw firmly, and holding down its head, began to crunch it. The cobra, however, being a very strong one, often got up again, and tried feebly to strike the mongoose; but the latter now bit its head and body as it pleased; and when the cobra became motionless and dead, the mongoose left it, and ran to the jungle.

The natives said that the mongoose went to the jungle to eat some leaves to cure itself. We did not wish to prevent it, and we expected it would die, as it was severely bitten.

In the evening, some hours after the fight, it returned, apparently quite well, and is now as well as ever. It follows either that the bite of a cobra is not fatal to a mongoose, or that a mongoose manages somehow to cure itself. I am not disposed to put aside altogether what so many intelligent natives positively assert.

This fight shows at any rate how these active little animals manage to kill poisonous snakes. On open ground a snake cannot strike them, whereas they can bite the body and tail of a snake, and wear it out before coming to close quarters. This mongoose did not seem to fear the cobra at all; whereas the cobra was evidently in great fear from the moment it saw the mongoose.

Ratnapura, Ceylon, April 11, 1871. R. REID

AUSTRALIAN PREPARATIONS FOR OBSERVING THE SOLAR ECLIPSE

THE following letter has been received at the office of the English Government Eclipse Expedition, from the Government Astronomer at Melbourne:—

"Melbourne Observatory, Nov. 4, 1871.

"My dear Sir,—The Eclipse instruments, copies of instructions, and your letter, reached me safely. Some of the instruments slightly damaged however, though not serious. About half the collodion bottles broken.

"The organisation of the Expedition is not yet quite complete; but a start, I think, is now certain. About 1,000*l.* has been contributed by various Australian colonies:—Victoria, 450*l.*; New South Wales, 300*l.*; South Australia, 100*l.*; Queensland, 100*l.*; and we expect to get 50*l.* from Tasmania. The cost of steamer, &c., will be from 1,400*l.* to 1,500*l.* Twelve or fourteen amateurs have joined, paying 30*l.* each for passage. The voyage will occupy about four weeks, including a week or ten days at Cape Sidmouth. The country at Sidmouth is quite unknown, and inhabited only by Aborigines, who, although not very warlike, are often exceedingly troublesome. Little is known of facilities for landing, &c., but as there are several coral islands in the vicinity, it is possible we may select some of them for observing stations, as they can easily be reached by laden boats. The whole of the coral sea inside the barrier reef is nearly always smooth water, so there cannot be much surf to contend with. The Expedition will have to start from here about the 20th instant.

"Now, about our equipment:—First, we have Grubb's integrating spectroscope, which, by-the-by, was considerably damaged; it had got adrift from its packing, and had evidently made sundry excursions of its own inside its case. Our instrument maker has set this right, and it is now in good working order, and I tried it with the hydrogen spectrum yesterday, and it performs satisfactorily.

"Second, the large field analysing spectroscope came out all right, only one reflector of the kind indicated available, and that altazimuth mounting, Browning 8-inch.

We can hear of no others. We are busy making equatorial mounting for this, but I am afraid we shall have no time to apply clock-work. One five-inch equatorial with its clock-work will be devoted to photographs, for this purpose the telescope will be dismantled and camera substituted, as no good can be done with both.

"Third, Photography. We shall have to confine ourselves to the operations with the camera as indicated in instructions, and we are doing all we can to ensure good results.

"Fourth, Polariscope work.—The two polarimeters are all right. Prof. Wilson, of our University, has offered to take charge of polariscope observations; his experience in experimenting on polarised light will ensure this part being thoroughly done if clouds permit.

"I think we thoroughly understand all the instruments and the instructions, and intend to take up such observations which appear from the latter to be most desirable, and for which we have instrumental means.

"We have sets of Kirchhoff's and Angström's maps here, we shall have several hand spectroscopes, opera-glasses, &c., provided for general observations.

"The little tube with the compound spectra of Mg, Ba, &c., appears to require Leyden jar and coil and a strong current, even then I am doubtful if it can be used.

"We take up one or two field instruments to determine position, &c.

"The observing party of Melbourne will number about nine, that from Sydney about six. We can at best only form two observing stations, and those not many miles removed from one another. Sydney observers, under Mr. Russell, will be engaged principally in photographs with refractor and spectrum work (analysing), and possibly we shall be able to arrange some polariscopes for them.

"I shall send you the earliest possible information of our success or otherwise on our return, which will be about Christmas.

"Our chances of fine weather are somewhat doubtful, as the cloudy N.W. monsoon generally sets in about the middle of December; it appears, however, that this seldom fairly sets in till after Christmas, and as the eclipse takes place on the 12th, we have some reason to hope for success.

"We are trying to get a recording spectroscope ready, but I am afraid there is scarcely time to finish it. The small telescope has a loose tube around it, covered with paper. The eye-piece and pointer slip across the field, and are made to do so by a long lever, moved by a pricking frame.

"ll is a loose tube forming recording barrel, bb is attached to eye-piece by flat spring, ll long lever pointed at a, h slide bar parallel to telescope, p pricker frame which slides along bb crossing eye-piece and pointer to traverse field (the lever and slide bar are drawn too parallel, they should be more inclined to one another). By moving p up and down the slide bar the pointer is made to coincide with a line, and the pricker p is pressed—after pricking one set the loose tube is slightly revolved, and a second set obtained. It is nearly complete, but has not been tried yet. I hope you will have good success in India.

"At Cape Sidmouth we shall have 3m. 34s. totality, the sun at an altitude of about 45°, a more convenient position than I thought before the data were computed. Like you, we are working almost night and day to get ready, for it was only a fortnight ago I had authority from Government to organise a party and prepare instruments. Again wishing you the best success,

(Signed) "ROB. L. J. ELLERY
"J. NORMAN LOCKYER, ESQ."

ELECTROPHYSIOLOGICA :

SHOWING HOW ELECTRICITY MAY DO MUCH OF WHAT IS
COMMONLY BELIEVED TO BE THE SPECIAL WORK OF A
VITAL PRINCIPLE

II.

2. *How Electricity may do much of what is commonly believed to be the work of a vital principle in muscular action.*

I HAVE long held that a vital property of "irritability," or "tonicity," was unnecessary in muscular action. As it seemed to me, the state of relaxation in living muscle was to be accounted for by the mutual repulsion of molecules arising from the presence in the muscle at the time of a charge of electricity, sometimes positive, sometimes negative; as it seemed to me, muscular contraction, whether in ordinary muscular action or in rigor mortis, was nothing more than the result of the operation of the elasticity of the muscle upon the discharge, sudden or gradual, of the charge which had previously kept up the state of relaxation. And I still hold that the state of relaxation is caused by the presence in the muscle of a charge of electricity, and that muscular contraction is brought about by the elasticity of the muscle coming into play upon the discharge of this charge; but, since I began to work with the new Quadrant Electrometer of Sir Wm. Thomson, I have been obliged to take a different view of the way in which the charge operates in causing relaxation. The fact, discovered by means of this instrument, that there are two charges of electricity in muscle, positive and negative, was fatal to the idea that the state of relaxation was due to the mutual repulsion of molecules consequent upon the presence in muscle of a single charge, positive or negative. With either charge singly the idea might be entertained, though it was not easy to understand how, wanting effectual insulation, the electricity could be kept to its work; with two opposite charges, on the contrary, the attraction of each charge for the other *must* neutralise the repulsion arising from the presence of either singly. Nor did I find a way of escape from this difficulty until I began to seek it in a totally different direction, even in the theory according to which the sheath of muscular fibre during rest is charged as a leyden-jar is charged. Is it possible, I asked myself, that the two opposite charges, disposed leyden-jar-wise upon the two surfaces of the sheath, may cause elongation of the fibre by compressing between them the elastic sheath? Opposite charges of electricity *must* attract each other; that was plain enough. Opposite charges attracting each other across an elastic sheath *may* compress that sheath in such a way as to cause elongation of the fibre; that was not impossible. Upon this view, too, there was no difficulty in understanding how each charge was prevented from escaping, and made to work in this manner, by the mutual attraction of each for the other. In a word, the idea that the two charges might act in this way in causing muscular relaxation was far more easy to realise than that which regarded the state of relaxation as the result of the muscular molecules being kept in a state of mutual repulsion by the presence of one charge in the muscle. And so it was that it became necessary to look into this matter a little more closely—to put it to the test of experiment, as best I could.

In order to this, I began by inquiring whether the idea in question was possible or not. I wanted to be certain that the mutual attraction of two charges of electricity, dispersed leyden-jar-wise upon the two surfaces of the sheath of the fibre, would cause elongation, and that the discharge of this charge would be followed by contraction; and, after several abortive attempts, I found what I wanted, and more than I expected at first, by the means which are represented in the accompanying figure.

Vulcanised india-rubber sheeting being at once elastic

and dielectric, it occurred to me that this material was the very thing for putting to the test of experiment what I believed might happen in the elastic and dielectric sheath of muscular fibre. I therefore took a band of this sheeting, provided it with the conducting surfaces necessary for charging and discharging it as a Leyden-jar is charged and discharged, and had constructed an apparatus for showing whether or not the anticipated changes in length were produced by this charging and discharging. The band (which is to be regarded as the counterpart of a *strip* of the actual sheath of the muscular fibre) is 14 in. in length by 2 in. in breadth, the commercial number of the india-rubber sheeting being 30. The necessary conducting surfaces to allow of the charging and discharging are made by painting the band on each side with fluid dutch-metal, care being taken to leave at the edges a sufficient unpainted margin to secure the necessary insulation of the two painted surfaces. The frame-work of the apparatus consists of two strong brass pillars, 18 in. in height, and 4 in. apart, rising from a flat brass stand. Across these pillars work two axes, horizontal in direction and parallel to each other—the one at the top, the other near the base, immediately above the stand. At the middle of the upper axle, midway between the pillars, is a wheel with a grooved edge, 2 in. in diameter, which may be called the driving-wheel; at one end, which projects beyond the pillar on that side, is another and larger wheel, 6 in. in diameter, also with a grooved edge, which may be called the multiplying-wheel. At one end of the lower axle, beyond the pillar on that side and immediately under the multiplying-wheel is a collar with a grooved edge; at the other end, also beyond the pillar on that side, is a socket for carrying a long index, of which the free end moves backwards or forwards before a graduated arc fixed immediately over the socket upon the same pillar near its top. The two axes move together, the upper telling upon the lower by means of an endless band which at one and the same time bites in the grooved edge of the multiplying-wheel at the end of the one, and in that of the collar at the end of the other; and thus the movements of the index before the graduated arc are made to represent a very considerable exaggeration of the movements of the upper axle. The india-rubber band is clipped at each end in a clamp, acting by screws, and having a hook on its free edge; and, being so clipped, it is fixed in a vertical position by passing the hook on the clamp at its lower end into a socket provided for it on the stand, and by attaching the hook on the clamp at its upper end to a string which passes over the grooved edge of the driving-wheel to a short hanging rod with a button at its lower end, upon which rod are to be slipped coin-like weights, notched in the centre for this purpose, which weights have to be so adjusted as to put the band gently upon the stretch. In this way the band is so fixed that it cannot lengthen or shorten without these changes being made to tell upon the index, for as it lengthens or shortens, the driving-wheel which moves the index must be made to turn this way or that by the string which bites into its grooved rim in passing from the band to the weights. For charging and discharging, two short pillars are fixed to the stand in front of and at a short distance from the bottom of the band, that for the former purpose having an ebonite shaft, that for the latter being altogether metal; and through holes in the caps of these pillars the rods which are intended to serve as the actual channels for the charge and discharge are made to slide horizontally backwards or forwards in a suitable direction. In charging, the electricity is supplied to the metallic surface on the front of the band by pushing forwards the charging rod so as to touch this surface, and at the same time taking care that the discharging rod is drawn back so as to leave the necessary break in the circuit. In discharging, the discharging rod is pushed home so as to complete the circuit between the two opposite

metal coatings of the band by touching the centre of the charging rod. And for the rest, all that need now be said of the apparatus (this is not all that has to be said, but what remains has to do with a totally different set of experiments, and had better be reserved until the time comes for dealing with these experiments) is, that in order to allow of this charging and discharging, the metal surface at the back, instead of being insulated all round like the metal surface at the front of the band, is put in communication with the earth by bringing it down a little so as to allow it to be clipped by the metal clamp which fixes the band to the stand.

In the actual experiment with the band, all that has to

be done is first to charge and then to discharge, watching the index the while. It was anticipated that the band would elongate with the charge, and shorten with the discharge, and this is what happens in fact; for on charging, the index at once moves before the graduated arc in the way which shows that the band elongates in proportion to the charge, and on discharging it suddenly jumps back again to the position it occupied before the charging, these forward and backward movements being through 40° or 60° , or even over a still wider range, and not merely through one or two degrees. The band plainly elongates in proportion to the charge. The band as plainly shortens in proportion to the discharge, suddenly or gradually, as the

case may be, suddenly if the charge be augmented until it overlaps the barriers of insulation, or if the discharge be brought about by pushing home the discharging-rod, gradually if the band be charged and then left to discharge itself slowly by keeping back the discharging-rod. And these results are constant, provided only before charging and discharging the weights attached to the band are so adjusted as to balance without overbalancing the elasticity of the band—a matter which is easily managed with but little patience and practice.

All, in fact, that was anticipated is fully borne out by the experiment. And thus it may be taken for granted that elongation of the muscular fibre *may* be caused by the attraction of two opposite charges of electricity

disposed leyden-jar-wise upon the two surfaces of the sheath of this fibre, and that contraction of this fibre *may* follow the discharge of these charges; for what is assumed to happen in this case is nothing more than what does actually happen with the band of india-rubber sheeting under perfectly analogous circumstances.

But if this be the way in which muscular fibre may be affected by its natural charge and discharge, how will it be affected by an artificial charge of the same kind? Will this artificial charge—the sheath being still a dielectric—act like the natural charge, the charge imparted to one side of the sheath inducing an equivalent amount of the opposite charge on the other side? Will the artificial charge, presuming it to be larger in amount than the natural

charge, overrule the natural charge? Will the artificial charge, thus larger in amount than the natural, produce a greater degree of elongation in the muscular fibre than that which is natural to the fibre? Will the contraction following the discharge of this artificial charge be greater in amount than that which is natural to the fibre, because the elasticity of the muscle has freer play under these circumstances? These questions, and others also of a like nature, are suggested by the experiment upon the elastic band; for not only does the band elongate with the charge and shorten with the discharge, but the elongation and shortening are manifestly in proportion to the amount of the charge and discharge. Nor are these questions unanswerable. On the contrary, answers may be found in more ways than one—in the examination of the phenomena of electrotonus more particularly; and these answers are in no way ambiguous in their meaning.

In electrotonus are strange modifications of muscular action. In electrotonus, too, as I have shown elsewhere,* are strange modifications of the electric condition of the parts, there being everywhere in the region of anelectrotonus a positive charge overflowing from the positive pole of the battery employed in the production of electrotonus, there being everywhere in the region of cathelectrotonus a negative charge overflowing from the negative pole of the same battery. In anelectrotonus there is a positive charge, not only present, but at work; in cathelectrotonus there is a negative charge, not only present, but at work. At work certainly, for as I have shown, the movements of the needle of the galvanometer characteristic of electrotonus are caused by the movement, not of a voltaic current, but of these charges through the coil of the instrument, the movement of cathelectrotonus by the flow of the negative charge, that of anelectrotonus by the flow of the positive charge. At work also, as I have also shown, in modifying muscular action. At all events, the presence of a positive charge in anelectrotonus and of a negative charge in cathelectrotonus are facts, and therefore I am justified in looking to the phenomena of muscular action in the two electrotonic states with a view to find answers to the questions now under consideration.

At the onset of the inquiry, however, a grave difficulty has to be coped with—a difficulty as to facts, for the actual facts are not what they are believed to be. In a word, it is not true that the action of anelectrotonus upon muscular action is essentially different from that of cathelectrotonus. Differences there are no doubt, but not any that will prove to be of moment in the present place. It is a fact that muscular action is suspended, not in anelectrotonus only, but in cathelectrotonus as well as in anelectrotonus. It is a fact that muscular *elongation* is a phenomenon common to both electrotonic states. Nor are these the only points in the history of electrotonus which require to be looked into carefully. So that, before proceeding further in this matter, it is necessary to ascertain what are the facts which have here to be dealt with.

The true history of muscular action during electrotonus may be well seen in the gastrocnemius of a frog by means of certain experiments for the exhibition of which the apparatus already used in the experiment with the elastic band is furnished with certain parts which have yet to be described. These parts consist of a pillar and a platform resting upon it horizontally, the pillar rising from the side of the stand opposite to that occupied by the charging and discharging rods. The pillar has a telescope arrangement, by which its length may be altered, and a screw-collar, by which it may be fixed at any length. The platform consists of a four-sided metal floor, five inches in length by three in breadth, with a narrow and rather thick border of ebonite in which are two binding screws for holding electrodes upon each of its sides, with a long roller at one of its ends, and with a moveable gutta-percha cover of such a shape and size as to allow it to be slipped on

and off between the ebonite borders, and fixed when on by having its edges made to play under the hollowed-out inner margins of the borders. In the actual experiment what has to be done is—to remove the elastic band and the weights attached to it—to fix the platform, so that it is a little behind and above the level of the driving-wheel, with the end to which the roller is attached turned towards this wheel—to fix the wires from the battery and induction apparatus to the binding-screws on the platform, the wires from the battery being carried to the side on which the screws are farthest from the roller (the battery, I should have said, consists of four medium-sized Bunsen-cells, and the induction-apparatus is one in which the secondary coil may be slipped altogether away from the primary—a Du Bois-Reymond's inductorium, in fact),—to prepare a frog's limb by stripping off the skin and dissecting away all parts of the thigh except the sciatic nerve,—to remove the gutta-percha cover from the platform, and pin upon it the prepared limb with its heel close to one end, care being taken not to injure the nerve or muscle in doing this,—to tie to the tendo-achillis the string which belongs to the weights,—to put back the gutta-percha cover into its place with the limb thus pinned and arranged upon it, the string attached to the tendo-achillis being brought out over the end which comes next to the roller,—to carry this string over the driving-wheel to the rod carrying the weights,—and to adjust these weights so as to put the gastrocnemius gently on the stretch,—and lastly, to draw out the nerve, and carry it first across the electrodes belonging to the induction-apparatus and then across those belonging to the battery, these electrodes, to allow of this, being made to point inwardly to a sufficient distance across the platform, two from one side, two from the other. In this way, when the circuits are closed (they are open at first) the nerve may be acted upon by voltaic and faradaic electricity as in an ordinary experiment in electrotonus. In this way, any change in the length of the gastrocnemius must tell upon the index, just as the changes in the length of the elastic band were made to tell, only in the contrary direction.

These arrangements being made, two experiments have to be tried, the one for exhibiting the action of anelectrotonus upon the gastrocnemius, the other for exhibiting that of cathelectrotonus, and each differing from the other only in the relative position of the voltaic poles, the positive pole being next to the insertion of the nerve into the muscle in anelectrotonus, the negative pole being in this position in cathelectrotonus.

In the experiment for exhibiting the action of anelectrotonus upon the muscle—that with the positive pole in the position next to the insertion of the nerve into the muscle—there are three distinct steps, the first taken before setting up the state of anelectrotonus, the two others after this time.

The first step, or that which is taken before the establishment of anelectrotonus, is to tetanise the muscle with faradaic currents only just strong enough to act upon the muscle at all in this way. In this case the circuit of the induction-apparatus is closed, but not that of the voltaic battery, and therefore the nerve is acted upon by faradaic currents before the establishment of anelectrotonus. At first, the faradaic currents used are strong enough to tetanise the muscle effectually; then these currents are weakened by drawing away the secondary coil from the primary until the tetanus comes to an end; last of all, the tetanus is brought back again to the very slightest degree by moving the secondary coil back again towards the primary coil, and leaving it at the point where the currents produced in it just begin to have a tetanising action. This is the first step in the experiment.

The second step consists in the establishment of anelectrotonus while the nerve is still being acted upon by these feeble faradaic currents. Hitherto the circuit of the induction apparatus was closed, while that of the voltaic

* "Dynamics of Nerve and Muscle," Macmillan, 1870.

battery was left open. Now the latter circuit is also closed, and with this result—that the index gives a sudden great jump in the direction showing contraction, and then, immediately moving in the opposite direction to that signifying contraction, takes up a position on the other side of zero—at 15° or 20° , it may be—a movement showing, not contraction, therefore, but elongation. Eliminating, as non-essential, the strong contraction which happens at the closing of the circuit—for this has to do, not with anelectrotonus, but with the *extra-current* which traverses the nerve between the poles at the closing of the voltaic circuit—what happens, therefore, on the establishment of anelectrotonus is, first, *suspension of the tetanus* caused by the feeble faradaic currents; and, secondly, *elongation of muscle*. This is the second step of the experiment, and these the results.

The third step follows upon the second. Its object is to ascertain whether the tetanus may be made to return during anelectrotonus by slightly increasing the strength of the faradaic currents acting upon the nerve; and the way of arriving at this is to leave the voltaic circuit still closed, to go on moving the secondary coil of the induction apparatus nearer to the primary, and to stop the moment the faradaic currents acquire strength enough to call back any tetanus. And this is what happens—that after moving the secondary coil but a short distance towards the primary, the index shows, not only that the tetanus has reappeared, but that it has reappeared in greater force. Before the establishment of anelectrotonus, the tetanus caused by faradaic currents only just strong enough to tetanise the muscle carried the index to 20° or thereabouts; after the establishment, the tetanus caused by faradaic currents only just strong enough to exert a tetanising action moved the index to 45° or 60° . In a word, contraction may happen in anelectrotonus, and when it happens it is considerably increased in amount. This is the third step of the experiment, and this the result.

In the experiment for exhibiting the phenomena of cathelectrotonus—that in which the negative voltaic pole is placed next to the insertion of the nerve into the muscle—all the steps are the same, and so are the results. The setting up of cathelectrotonus suspends the tetanus caused by feeble faradaic currents, and causes elongation in the muscle. The tetanus brought back during the cathelectrotonus by currents only just strong enough to have a tetanising action is in increased force. The degree of elongation is the same as in anelectrotonus. The increase of contraction is the same as in anelectrotonus. The only difference, indeed, between the two experiments is this, that somewhat feeble faradaic currents serve to recall the tetanus in cathelectrotonus than those which were required to do this in anelectrotonus.

Nor are these facts at variance with those which are brought to light when the state of electrotonus is produced by a smaller amount of battery power—by a single element, for example. In this case it often happens (not always) that the tetanus caused by salt or very feeble faradaic currents is suspended by anelectrotonus, and intensified by cathelectrotonus. It seems as if there was an essential difference between this action of the two electrotonic states upon nerve and muscle, but after what has just been seen this is by no means a necessary conclusion. It has been seen that anelectrotonus has a greater power of suspending tetanus than cathelectrotonus, therefore tetanus may be suspended by anelectrotonus when it is not suspended by cathelectrotonus. It has been seen that during both anelectrotonus and cathelectrotonus contraction when it happens is greater than that which happens in the non-electrotonised state; and therefore, during cathelectrotonus, if tetanus be not suspended, it is likely to be intensified. This is all. The facts are in keeping with those which have gone before when they are properly looked into, and there is no ground in them

for supposing that there is an essential difference between the action of anelectrotonus and cathelectrotonus—no ground for supposing that the effects of using a small battery power in the production of electrotonus are in any way different from those which attend the use of a larger power of this kind.

C. B. RADCLIFFE

CONJOINT MEDICAL EXAMINATIONS*

WE are able to open the new year with the satisfactory announcement that the last difficulty has been removed which impeded the action of the great medical examining incorporations of England in uniting to frame a conjoint scheme for a minimum examination, which will constitute, in fact, a single and uniform portal to the profession. All the committees of the bodies concerned have signified their approval of the following scheme:—

In view of the legal difficulties which have been stated by the Society of Apothecaries to prevent that society taking part in the formation of an examining board in this division of the United Kingdom, it was resolved:

I. That a board of examiners be appointed in this division of the United Kingdom by the co-operation of the Royal College of Physicians of London, the Royal College of Surgeons of England, and of such other of the medical authorities in England, mentioned in Schedule (A) to the Medical Act, as may take part in its formation; it being understood that, liberty being left to such co-operating medical authorities to confer, as they think proper, their honorary distinctions and degrees, each of them will abstain from the exercise of its independent privilege of giving admission to the "Medical Register."

II. That the Board be constituted of examiners, or of examiners and assessors appointed by the several co-operating medical authorities.

III. That examiners be appointed on the following subjects: Anatomy and physiology; chemistry; materia medica, medical botany, and pharmacy; forensic medicine; surgery; medicine; midwifery; or on such subjects as may be hereafter required.

IV. That no examiner hold office more than five successive years, and that no examiner who has continued in office for that period be eligible for re-election until after the expiration of one year.

V. That the examiners be appointed annually by the several co-operating medical authorities on the nomination of a committee, called herein "The Committee of Reference;" but no member of the Committee of Reference shall be eligible for nomination as an examiner.

VI. That a Committee of Reference, to consist of an equal number of representatives of medicine and surgery, be appointed as follows: One representative of medicine and one representative of surgery to be appointed by each of the Universities in England; four representatives of medicine to be appointed by the Royal College of Physicians of London; four representatives of surgery to be appointed by the Royal College of Surgeons of England.

VII. That one-fourth of the Committee of Reference go out of office annually, and that, after the first four years, no retiring member be re-eligible until after the expiration of one year.

VIII. That the duties of the Committee of Reference be generally as follows: 1. To determine the number of examiners to be assigned to each subject of examination. 2. To nominate the examiners for appointment by the several co-operating medical authorities. 3. To arrange and superintend all matters relating to the examinations, in accordance with regulations approved by the co-operating medical authorities. 4. To consider such questions in relation to the examinations as they may think fit, or such as shall be referred to them by any of the co-ope-

* Reprinted from the *British Medical Journal*.

rating medical authorities, and to report their proceedings to all the said authorities.

IX. That there be two or more examinations on professional subjects, and that the fees of candidates be not less than thirty guineas to be paid in two or more payments.

X. That every matriculated student of an English university who shall have completed the curriculum of study required by his university, and shall have passed such an examination, or examinations, at his university as shall comprise the subjects of the primary examination, or examinations, conducted by the Board, be eligible for admission to the final examination; and that every candidate so admissible to examination be required to pay a fee of five guineas, but he shall not be thereby entitled to the license of the Royal College of Physicians of London, nor to the diploma of member of the Royal College of Surgeons of England, without the payment of an additional fee of not less than twenty-five guineas.

XI. That every candidate who shall have passed the final examination conducted by the Board shall, subject to the by-laws of each licensing body, be entitled to receive the license of the Royal College of Physicians of London, and the diploma of member of the Royal College of Surgeons of England.

This is signed by George Burrows, President of the Royal College of Physicians, and George Busk, President of the Royal College of Surgeons.

Sir Roundell Palmer, Mr. Denman, and Mr. Bevis have given their opinion that this scheme can be legally carried into effect by means of by-laws to be adopted by the respective Colleges of Physicians and Surgeons. This opinion was presented at the meeting of the Joint Committee on the 3rd inst. The examiners in surgery will be chosen from among the examiners who have been appointed under the charters of the College of Surgeons, and the Court of Examiners will adopt the certificate of the new examining body.

Meetings are being held in Dublin with a view to the formation of a conjoint examining board for Ireland. So far, no insurmountable difficulty has arisen in the several matters which have come under the notice of the deputed representatives of the Universities and of the other licensing bodies, and it is hoped that the board, as proposed, will become an accomplished fact. A claim was put forward by the Universities that the first part of the professional examination conducted by the conjoint board should not be required of university students who had passed their examination on the same subjects; and that in their case the examination should be confined to the final one. To this, however, the other licensing bodies properly objected; but an offer has been made by the other corporations that the preliminary examination should be wholly conducted by examiners appointed by the Universities.

NOTES

THE celebrated ethnological collection of the late Dr. Gustavus Klemm, of Dresden, which had obtained a world-wide celebrity from its richness in illustrations of dress and ornaments, household utensils, furniture, warlike, fishing, and hunting implements, &c., extending from the earliest times down to the immediate present, has been purchased by subscription, and transferred to Leipzig, where it forms the nucleus of the new German Central Museum of Ethnology, and around which is to be grouped whatever additional material can be procured in illustration of the general plan. An earnest appeal is made by the officers and others interested in this enterprise to their countrymen and others in the United States for contributions. It will occupy the place in Germany of the great Archaeological Museum of Copenhagen: of that of Mr. Blackmore at Salisbury, in England;

of the Museum of St. Germain, near Paris, under direction of M. Mortillet; and of the Smithsonian and Peabody Museums in the United States.

THE Exhibition of Neolithic Instruments by the Society of Antiquaries at Somerset House will be re-opened to-morrow, and will finally close on Thursday, January 18. For tickets apply at the Society's apartments.

ON Saturday last, at an early hour in the morning, the female hippopotamus in the Zoological Society's gardens gave birth to a young one—being the second occasion on which this interesting occurrence has taken place. As in the former case, it has been found necessary to close the building in which the female is placed entirely, not even the keepers entering into it except when absolutely necessary, in consequence of the extreme savageness and jealousy exhibited by the fond mother. Some days must therefore elapse before the "little stranger" can be prepared to undergo the ordeal of public exhibition.

ANOTHER interesting addition just made to the Zoological Society's collection is a young specimen of the King Penguin (*Apteryodes pennanti*) from the Falkland Islands. For this remarkable bird, which is still in the down-plumage, the Society are indebted to the kind exertions of F. E. Cobb, Manager of the Falkland Islands Company, who has been for some time endeavouring to obtain living examples of this species for the Society. The King Penguin is placed in the great eastern aviary, along with a specimen of the Cape Penguin (*Spheniscus demersus*) which has been for some time under the Society's care.

WE have just received the fourth report of the Radcliffe Trustees from the Radcliffe Librarian, Dr. Henry W. Acland, including also a catalogue of the transactions of societies, periodicals, and memoirs, available for the use of professors and of students in the Library; a catalogue of books recommended to students in physical science by the museum professors; and the Regulations of the Library. The additions to the Library are made, as far as the annual grant of 500*l.* will allow, either on the judgment of the librarian as to the intrinsic value of a work, or on the advice of a professor, or upon the knowledge that students require it.

It is stated that the average yearly number of visitors at the South Kensington Museum during the last five years has been 905,084.

THE University Court of the University of Edinburgh, at a meeting held on Tuesday, Jan. 2, declined to give effect to the recommendation of the Senatus, that the regulations in reference to the medical education of women should be rescinded. The Court guarded itself against being understood to indicate any opinion as to the claim of women to proceed to graduation, or as to the powers of the University to confer on women degrees in the faculty of medicine.

THE Second Course of Cantor Lectures of the Society of Arts for the session will be delivered by the Rev. Arthur Rigg, M.A., on "Mechanism." The first lecture will be given on Monday evening, Feb. 5, at eight o'clock, and the remainder of the course will follow on the five succeeding Monday evenings.

AT the annual meeting of the Birkbeck Literary and Scientific Institution, Sir John Pakington, M.P., in the chair, it was stated that, during the past year, the following new subjects have been introduced into the curriculum of the Institution:—Acoustics, Light and Heat, Practical Chemistry, Mineralogy, Metallurgy, and the Theory of Music.

THE authorities of the American Museum of Natural History, at the Central Park in New York, have set apart Monday and Tuesday especially for the use of those persons who may desire

to examine the specimens in the Museum for the purpose of special study. Notifications of this arrangement have been distributed to the principal learned societies throughout the country, inviting them to attend on these days.

DE LA RUE's indelible diaries for 1872 are as usual beautifully printed and bound, with ample room for memoranda. We miss the astronomical article, but still the letter-press being curtailed is an advantage, the book being less weighty for the pocket. The desk diary is a most useful appendage to the writing table, containing, besides the almanack, tables, &c., extra pages for memoranda and accounts.

The eighth Annual Report is issued of the Belfast Naturalists' Field Club for 1870-71. The papers of which abstracts are printed in the Report are of varied interest, the subjects comprised including—"The Geographical Distribution of Cyclones," "The Latest Fluctuations of the Sea Level on our own Coasts," "Ocean Currents and their Effect on Climate," "Report of a Committee appointed to examine some Ancient Remains in the neighbourhood of Armo, county Antrim," and numerous others. A number of prizes are offered to be competed for during the session ending March 31, for the best herbarium, collections of fossils, recent Crustacea and Echinodermata, shells, insects, sponges, &c., and others.

PROF. HALFORD has received from Simla the thanks of the Government of India for his paper on "The Treatment of Snake-bite by the Injection of Liquor Ammoniac into the Veins." The Governor-General in Council has determined to have Dr. Halford's pamphlet reprinted for general distribution to medical officers in different parts of India. It appears to be placed beyond doubt that this treatment is by far the most efficacious yet discovered in cases of poisonous snake-bite.

CONDURANGO root, the reputed specific for cancer, is becoming a subject of speculation in Ecuador and the United States. In Ecuador it has reached 17*l.* a ton, but in New York it has been selling for fabulous prices, though its virtues are contested. The Government of Ecuador has imposed an export duty. The Condurango root is now reported to have been discovered by Mr. Simmons in the neighbourhood of Santa Marta in Colombia or New Granada, and a small shipment has been made to the United States. It is not stated whether it has been tried for cancer in that country.

The Chilean Government has sent the war steamer *Chacabuco* to survey the islands of Guaiatecas.

The U.S. Government has directed a survey of the Bay of Limou, the Atlantic terminus of the new Costa Rica Railway, where a city is being laid out with a pier.

ANTHRACITE coal has been discovered in the district of San Miguel, five miles from the capital of Costa Rica in Central America. There are several seams of about 40 miles wide, and the coal has been proved to be of good quality. A railway is in progress in the neighbourhood. It may be remembered that coal is also found in the State of Panama.

It is noted as remarkable that a spring of fresh water has been discovered near Mollendo in Peru.

The pearl oysters are said to have disappeared this season from the Madras coast, as well as from that of Ceylon.

M. BERTILLON lately read before the Academy of Medicine in Paris a paper on the relative influence of marriage and celibacy, based on statistical returns derived from France, Belgium, and Holland. In France, taking the ten years 1857-66, he found that, in 1,000 persons aged from 25 to 30, 4 deaths occurred in the married, 10·4 in the unmarried, and 22 in widowers; in females at the same age, the mortality among the married and unmarried was the same—9 per 1,000, while in widows it was 17. In persons

aged from 30 to 35, the mortality among men was, for the married, 11 per 1,000, for the unmarried, 5, and for widowers, 19 per 1,000; among women, for the married, 5, for the unmarried, 10, and for widows, 15 per 1,000. There appears to be a general agreement of these results of marriage in Belgium and Holland, as well as in France.

We are so accustomed to associate tattooing almost entirely with the natives of New Zealand and the Indians of North America, that it comes to us almost as a new fact to learn from a correspondent of the *Field* what a high standard the art of tattooing has reached among the Japanese. There we find men who make it their business to tattoo others, and these "professors of tattooing" are artists of no mean power, "for no india-rubber or ink-eraser can possibly take out a false line once imprinted; and they most invariably in the 'printing in' improve upon the drawings previously made." The bettoes or Japanese groomers will frequently have depicted on their skins, not only perfectly-drawn pictures of birds, reptiles, beasts and fishes, but also representations of whole scenes, often from some old legend or history. A very common device is the red-headed crane, the sacred bird of Japan, depicted standing on the back of a tortoise, and this is emblematic of woman's beauty treading down man's strength. These designs are pricked in by needles, and two or three colours are used.

PROF. KENGOTT, of Zurich, states that a hail-storm lasting five minutes occurred at eleven o'clock in the morning of August 20, 1871, the stones from which were found to possess a salty taste. Some of them weighed twelve grains. They were found to consist essentially of true salt, such as occurs in Northern Africa on the surface of the plains, mainly in hexahedric crystals or their fragments, of a white colour, with partly sharp and partly rounded grains and edges. None of the crystals were entirely perfect, but appeared as if they had been roughly developed on some surface. They had probably been taken up and brought over the Mediterranean from some part of Africa, just as sand is occasionally transported thence to the European continent and the Canaries by means of hurricanes. A still more remarkable phenomenon has been recently recorded by Prof. Eversmann, of Kasan—namely, the occurrence of hailstones, each containing a small crystal of sulphuretted iron. These crystals were probably weathered from some rocks in large quantity, and were then taken up from the surface of the ground by a storm, and when carried into the hail-forming clouds served as a nucleus for the formation of hailstones.

A PRACTICAL extension of the metalliferous region of Chile to the south is announced in the discovery of rich silver deposits in the southern province of Nuble. The place is called Cuesta del Caracol, and is between the Rivers Lota and Nuble, about fifty miles from San Carlos towards the east. The standard on assay is estimated at 100*lb.* of silver to the ton. Operations are already prepared on a large scale. The Lota district has hitherto only been known for its large trade in coal and fire-bricks.

THE Indian Government has taken measures for a survey of the Tenasserim tin mines and their present state of production, for which purpose it has despatched Mr. Mark Fryar, mining engineer, to that province.

In the native State of Kolapore in the Bombay Presidency sheep suffered from a strange form of animal plague. This consists of a swarm of unusually voracious leeches. Besides this the wolves were out, carrying off children, invalids, and the aged in the exposed villages.

A white elephant having been discovered in our possessions in Tavoy, on the Malay Coast, the Buddhist sovereigns are extremely anxious to obtain such an important minister of religion.

The King of Burmah has made special application to be favoured with the holy beast.

AN earthquake took place at Valparaiso in the early part of November (date not given) at 10.5 P.M. The shock was smart, and apparently from E. to W. There was another slighter shock shortly after midnight.

ON Oct. 10 an earthquake was felt at Salvador, also in Central America, at 8.27 A.M. It was slight. Another was felt on the 12th, at 11.36 P.M., lasting nineteen seconds, with a strong shock. After the 12th were two slight shocks, it is to be supposed conforming with those of Nicaragua.

ON Sept. 25 an earthquake was felt at Carrizal Bajo, in North Chile, at 4.3 P.M., preceded by a loud noise.

THREE islands have lately been surveyed by the United States Government in the North Pacific Ocean. They are Ocean Island, in latitude 28° 25' N., longitude 178° 25' W. Midway Island, or Brooks Island, in latitude 28° 15' N., longitude 178° 20' W.; Pearl and Hermes Islands, latitude 27° 50' N., and longitude 175° 50' N. They are all three coral islands, and abound in turtle, and birds were found in great numbers. There is but little guano and not much vegetation.

IN connection with the bad weather in November in the Bay of Bengal, the telegraph lines were on the 10th affected by earth-quake on the east coast of India. At Madras these currents were first noticed at 6 A.M., they abated at 4 P.M., and were strongest in the lines forming a considerable angle with the magnetic meridian. They were also observed in the Madras cable. In Calcutta the currents were noticed at about 3 A.M. and ceased at 2 P.M.

ANCIENT ROCK INSCRIPTIONS IN OHIO*

SEVERAL diagrams were presented to the section representing rock sculptures in Ohio, that are presumed to be ancient and to have some significance. The largest is a tracing made by Dr. J. H. Salisbury, of Cleveland, with the assistance of Mrs. Salisbury, from a mural face of conglomerate, near the famous "Black Hand" in Licking County, Ohio. Once there was a space of ten or twelve feet in height, by fifty or sixty feet in length, covered by these inscriptions. Most of them have been obliterated by the recent white settlers.

In 1861, Dr. Salisbury took copies from a space about eight by fifteen feet, by laying a piece of coarse muslin over them, and tracing such as remain uninjured, life size, on the cloth. In this space there are found to be twenty-three characters, most of which are the arrow-head or bird-track character. These are all cut on the edge of the strata, presenting a face nearly vertical, but a little shelving outward, so as to be sheltered from the weather.

Another copy of the remnants of similar inscriptions was taken by Colonel Whittlesey and Mr. J. B. Comstock, in 1869, from the "Turkey Foot Rock," at the rapids of the Maumee, near Perrysburg. These are on a block of limestone, and in the course of the twenty-five past years have been nearly destroyed by the hand of man. What is left was taken by a tracing of the size of nature.

On the surface of a quarry of grindstone grit at Independence, Cuyahoga County, Ohio, a large inscribed surface was uncovered in 1854. Mr. B. Wood, Deacon Bicknell, and other citizens of Independence, secured a block about six feet by four, and built it into the north wall of a stone church they were then building. Colonel Whittlesey presented a reduced sketch, one-fourth size of nature, taken by Dr. Salisbury and Dr. J. M. Lewis, in 1869, which was made perfect by the assistance of a photographer. Some of the figures sculptured on this slab are cut an inch to an inch-and-a-half in the rock, and they were covered by soil a foot to eighteen inches in thickness, on which large trees were growing. Like all of the others, they were made by a sharp-pointed tool like a pick, but as yet no such tool has been found among the relics of the mound-builders or of the Indians. The figures

are very curious. Among them is something like a trident, or fish-spear, a serpent, a human hand, and a number of track-like figures, which the people call buffalo-tracks, but which Dr. Salisbury regards as a closer representation of a human foot covered by the shoe-pack or moccasin. Another figure somewhat resembles the section of a bell with its clapper.

Near the west line of Belmont County, Ohio, Mr. James W. Ward, then of Cincinnati, now of New York, in 1859 took a sketch of two large isolated sandstone rocks, on which are groups of figures similar to those already noticed. Here are the bird-track characters, the serpent, the moccasin or buffalo-tracks, and some anomalous figures. These are plainly cut, with a pick, into the surface of the rock, which, like the Independence stone, is substantially imperishable. Here we have also the representation of the human foot, and the foot of a bear. Another figure, which appears to be the foot of some animal with four clumpy toes, Prof. Cope thinks may be the foretrack of a Menopome. One peculiarity of these sculptured human feet is a monstrously enlarged great-toe joint, even greater than is produced by the modern process of shoe-pinching. This has been observed in other ancient carvings of the human foot upon the rocks near St. Louis, Missouri. These feet range in size from seven to fifteen inches in length. Of all these representations, the bear's foot is closest to nature. The bird-track, so called, presents six varieties, some of which are anatomically correct. The human hand is more perfect than the foot.

Dr. Salisbury finds, on comparison of these symbolical figures with the Oriental sign-writing, or hieroglyphical alphabets, that there are many characters in common. Some 800 years before Christ, the Chinese had a bird-track character in their syllable alphabet. The serpent is a symbol so common among the early nations, and has a significance so various, that very little use can be made of it in the comparison.

These inscriptions differ materially from those made by the modern red man. He is unable to read that class of them which appears to be ancient.

Lieut. Whipple has mentioned in the "Government Report of the Pacific Railroad Surveys," an instance of the bird-track character inscribed upon the rocks of Arizona. Prof. Kerr, of North Carolina, states that he has noticed similar characters cut in the rocks of one of the passes of the Black Mountains, at the head of the Tennessee river.

These facts indicate wide-spread universality in the use of this style of inscription, and they indicate something higher than the present symbolical or picture writing of the North American Indians.

SCIENTIFIC SERIALS

Monthly Microscopical Journal, January.—"The markings on the Battledore scales of some of the Lepidoptera." By John Anthony, M.D., &c. In this paper the author contributes the result of his observations on the plumules of *Polyommatus Alexis*, from which he is led to the conclusion that the markings on the ribs of the scales are elevations, very much resembling in shape the vegetable glands on the petal of *Anagallis*, that is, the elevations have a base, a column, and a rounded head, or capital; the form being very much like that of an ordinary collar-stud. The methods employed during observation are detailed in the paper, which is illustrated by two plates.—"The Nerves of Capillary Vessels and their probable action in health and disease." By Dr. Lionel S. Beale, F.R.S. This paper is divided into two parts, the anatomical investigation, and probable mode of action. The first part, containing the results of anatomical investigation alone, is published in the current number of the journal. The sections of this paper are, "Structure of Capillaries," "Nuclei or Masses of Bioplasm of Capillaries," "Nerve Fibres," "Arrangement of the Nerve Fibres distributed to the Capillaries," "Central Origin and Peripheral Connections of Nerve Fibres distributed to the Capillaries," and the "Method of Demonstration." Such an important contribution to microscopic anatomy could not be abstracted within the limits of this notice with justice to the author and his subject. We therefore commend it to the notice of all interested therein, with the assurance that they will find much matter for reflection.—On a New Micrometric Goniometer Eye-piece for the Microscope. By J. P. Southworth. The eye-piece micrometer here described is obtained by photographic reduction from heavy India-ink lines drawn on a white Bristol board. In the micrometer the lines are $\frac{1}{250}$ of an inch apart, and jet black, whilst the spaces between them are trans-

* Paper read before the American Association for the Advancement of Science, Section of Archaeology, by C. Whittlesey. Reprinted from the *American Naturalist*.

lucent enough to admit of the accurate measurement of the details of minute algae and fungi to the $\frac{1}{1000}$ of an inch. The goniometer is also described. Both are said to possess advantages not secured before by any instrument. The remaining papers are—Note on Dr. Barnard's Remarks on the Examination of Nohbert's Nineteenth Band, by J. J. Woodward, Assist. Surg. U.S. Army; a New Erecting Arrangement, especially designed for use with binocular microscopes, by R. H. Ward, M.D.; and On the Action of Hydrofluoric Acid on Glass, viewed Microscopically, by H. F. Smith.

Of the *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève* the first part of the twenty-first has recently been published. It is chiefly occupied by an admirable memoir on the Orthopteroidea family Mantidae by M. Henri de Saussure, forming the third fascicule of his "Mélanges Orthoptérologiques." In this paper the author not only describes a great number of new species, but also discusses the internal classification of the family, and gives tables of the subordinate groups and genera, and the synonymy of nearly all the species, so that his work (including its supplement) is very nearly a monograph of the curious and interesting group of insects which constitutes its subject. A great number of the species described by the author are figured on four beautifully executed plates which accompany the memoir, and these will astonish the non-entomological reader by the variety of curious forms produced by modifications of the same plan of structure.—The other papers in this part consist of descriptions of new or little-known exotic Cryptogamia (Mosses), by M. J. E. Duby, illustrated with four plates; a paper on gelatiniform matter by M. Morin, and a report on the labours of the society by its President, M. Henri de Saussure.

PART II. of the *Bulletin of the Royal Swedish Academy of Sciences* (Öfversigt af Kongl. Vetenskaps Akademiens Förhandlingar) for the present year commences with a paper (in Latin), by Dr. E. Fries, containing a description of *Quelidia*, a new genus of Lycopodiaceae Fungi, and of a new species of the genus *Gyromitra*. The characters of the former are illustrated in a plate.—Another botanical paper is a notice of some Algae from the inland ice of Greenland, by M. S. Berggren. The author describes and figures a peculiar form, which he regards as most approaching the Zygnemaceae, but as having an unmistakable resemblance to some Desmidiaceae.—Passing by a rather wide step from Greenland to South Africa, we have Latin descriptions of 226 Caffrarian Carculionidae, collected by Wahlberg, from the pen of M. O. J. Fahreus. These all belong to Lacordaire's second division of the family.—M. B. Lundgren publishes a notice of the occurrence of amber at Fyllinge, in Halland.—The remaining papers are upon chemical subjects, and include a paper by M. P. T. Cleve on some remarkable isomerisms in organic chemistry; a paper by the same author on the nitrides of some platinum-bases; and one by M. L. F. Wilson on the sulphides of arsenic.

Journal of the Chemical Society, September 1871. Bolas and Groves have continued their researches on carbon tetrabromide, and have obtained some interesting results. In their former paper they mentioned that antimony tetrabromide could be substituted for iodine in the preparation of the tetrabromide. They now find that bromine will act on carbonic disulphide in the presence of the bromides of the following metals:—bismuth, arsenic, gold, platinum, cadmium, zinc, and nickel; the bromides of iron, tin, phosphorus, and sulphur, however gave very unsatisfactory results. The authors still think the mixture of bromine and iodine the most convenient reagent for the preparation of the tetrabromide. The authors recommend for the recovery of bromine from residues the action of dipotassic dichromate and sulphuric acid.—R. C. Woodcock has examined the action of ammoniac chloride on normal and acid salts; he has experimented on the following bodies:—potassic chromate, microsmic salt, trisodic phosphate, dipotassic tartrate, succinate, &c. By the action of ammoniac chloride on sodic metaborate the whole of the ammonia is evolved, sodic chloride and metaboric being formed. Borax also yields the whole of the ammonia, sodic chloride and tetrametaborate remaining behind. Both soluble and insoluble chromates yield ammonia when distilled with ammonia salts, an acid chromate being formed; the whole of the ammonia, however, is not evolved, the acid chromate formed at a certain point stopping the evolution of ammonia; if the acid salt be removed by crystallisation, a copious evolution of ammonia again takes place on boiling.—W. Mattieu Williams communicates a short abstract of a paper "On Burnt Iron and Steel." Iron which has been damaged by re-heating

is designated "burnt iron;" it is brittle, its fracture being short, displaying the so-called crystalline structure. In all the samples which the author has examined, he has found particles of black oxide of iron diffused in the mass. The oxidation must of course take place after that of the carbon present in the iron. It is found that iron attains its maximum toughness when the carbon is reduced to the lowest possible proportion without the oxidation of the iron commencing. When steel is raised to a yellow or white heat, and is suddenly cooled, it turns brittle. Burnt steel has a coarse, granular fracture, and contains small cavities, technically called "toads' eyes." These are probably due to the sudden cooling of the iron imprisoning the carbonic oxide, which is evolved by the oxidation of the carbon; this oxidation not only takes place at the surface of the mass, but also in the interior, from the fact that certain gases can pass readily through heated iron. This explanation is strengthened by "burnt steel" being cured by welding up these cavities. The remainder of the number is occupied with the abstracts of chemical papers, which extend over seventy-five pages, and are quite up to the usual standard, both in scientific interest and as regards literary merit.

Journal of the Chemical Society, November 1871.—This number does not contain any papers originally communicated to the Society. It is not certainly to the credit of English chemists that this should be the case for two months in succession; the number of English chemists who devote their time to original research seems every year to become smaller; on the Continent, however, the reverse is the case, as is shown by the very large number of abstracts, which are published monthly by the Society. This month about 130 papers are abstracted, which fill 127 pages. Amongst them we notice a remarkable communication by Angström "On the Spectra of Simple Gases." Angström took a tube filled with atmospheric air and gradually exhausted it by a mercurial pump, the spectra being obtained by the use of an induction coil. He states that he observed successively the following spectra: 1st, that of atmospheric air; 2nd, the band spectrum of nitrogen; 3rd, that of carbonic oxide; and 4th, when the rarefaction had reached its limit, the lines of sodium and chlorine. He has also experimented on hydrogen, and concludes that it possesses only one spectrum, that of four lines, which is observed in the spectra of the sun and stars. He believes that the various spectra of hydrogen obtained by Plücker, Frankland and Lockyer, Wöllner, and others, are entirely due to impurities, such as acetylene and sulphur.—An abstract of a paper by Andrews contains a curious fact. A fine tube is half filled with bromine and hermetically sealed; on heating, the bromine becomes opaque, so that the tube appears to be filled with a dark red resin.—Lieben and Rossi continue their researches on the normal alcohols and acids of the methyl series; a review of their results has already appeared in these pages.—Ladenburg contributes another most interesting paper, "On the reduction products of silica, ether, and some of their derivatives;" these researches are very important, and have opened out quite a new branch of chemical inquiry. He has obtained such bodies as silicium, diethylketonic ether ($\text{SiC}_2\text{H}_5\text{OC}_2\text{H}_5$), silicoheptyl ether ($\text{SiC}_2\text{H}_5\text{OC}_7\text{H}_{15}$), and so on.—Another paper of some interest is by Heinrich, "On the Influence of Heat and Light on the Evolution of Oxygen by Water Plants." He experimented on the leaves of the *Hottonia palustris*, which were placed in common water. At a temperature of 27°C . in full sunlight no evolution of gas took place, but at 56° a regular evolution commenced. The most active formation was at 31° , and at 50° to 56° gas ceased to be formed, but the leaf resumed its activity in cooler water. If the leaves were exposed to a temperature of 60° for ten minutes, their power of decomposing carbonic acid was destroyed.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, December 20, 1871.—Mr. Joseph Prestwich, F.R.S., president, in the chair. Mr. Frederick H. Dowman, F.R.A.S., F.C.S., of Halifax, Yorkshire, and Mr. Thomas Charles Sorby, B.A., F.R.S., of 27, Brunswick Square, W.C., were elected Fellows of the Society. The following communications were read:—1. A Letter from Mr. G. Milner Stephen, F.G.S., to the late Sir Roderick Murchison, dated Sydney, 5th October, 1871, announcing the discovery of a rich auriferous deposit on the banks of the River Bondé, on the N.E. coast of

New Caledonia, and of a great deposit of tin-ore in the district of New England, New South Wales. The gold in New Caledonia is found in drift, and there are indications of the near proximity of a quartz-reef. The tin-ore in New South Wales is said to be in "pepitas, crystals, and beds of conglomerate, especially in micaceous granite, more or less decomposed." Mr. D. Forbes stated that in 1859 he had placed in his hands some specimens of granite from the district the discovery of tin in which was announced by Mr. Stephen, and that he found them to be perfectly identical with the stanniferous granites of Cornwall, Spain, Portugal, Bolivia, Peru, and Malacca, which he had also examined. These granites were all composed of white orthoclase, felspar, colourless or black Muscovite mica and quartz. He was not aware that tinstone (cassiterite or oxide of tin) occurred anywhere in rock of a different character. It was always accompanied by more or less native gold. Mr. Pattison remarked that in many places where tin occurred it was not present in sufficient quantity to be remuneratively worked. Mr. D. Forbes, in answer to a question from Prof. Ramsay, stated that, as far as could be ascertained, the age of the stanniferous granites mentioned by him must be between the end of the Silurian and the early part of the Carboniferous period. Prof. Ramsay would carry them down to the close of the Carboniferous period, and would be contented to term them pre-Permian.—"Remarks on the Greenland Meteorites." By Prof. A. E. Nordenskjöld, For. Corr. G.S. The author stated that the masses of meteoric iron brought from Greenland by the recent Swedish expedition seem to have formed the principal masses of an enormous meteoric fall of miocene date, extending over an area of some 200 miles. The iron appears to be free from silicates. Against its eruptive origin the author urges that when heated it evolves a great amount of gaseous matter, and that it contains imbedded particles of sulphide of iron, the mass itself being nearly free from sulphur. The masses are composed of meteoric nickeliferous cast and wrought iron, or of mixtures of the two; in the last case the Widmannstetten's figures are best developed. The author further noticed the various modes in which the iron occurs, viz., 1, as meteorites; 2, filling cracks; 3, as breccia-form stones cemented with oxide and silicate of iron; and 4, in grains disseminated in the basalt. Mr. Roberts protested against the evolution of gaseous matter being considered as a proof of meteoric origin. Prof. Ramsay reiterated his previously-expressed opinion, that the masses of iron might be of telluric origin.—"Further Remarks on the Relationship of the *Limulidae* (*Xiphosura*) to the *Eurypteridae* and to the *Trilobita*." By Mr. Henry Woodward, F.G.S. In this paper the author described the recent investigations made by Dr. A. S. Packard, Dr. Anton Dohrn, and the Rev. Samuel Lockwood upon the developmental history of the North American King-crab (*Limulus Polyphemus*), and discussed the conclusions as to the alliances of the *Xiphosura* and *Eurypteridae*, and to the general classification of the *Arthropoda*, to which the results of these investigations have led Dr. Dohrn and some other Continental naturalists. According to this view, the *Xiphosura* and *Eurypteridae* are more nearly related to certain *Arachnida* (the Scorpions, &c.) than to the *Crustacea*; and this opinion is further supported by the assertion of Dr. Dohrn, that in *Limulus* only one pair of organs (antennules) receives its nerves from the supraoesophageal ganglion, and that the nature of the underlip in *Limulus* differs from that prevailing among the *Crustacea*. Dr. Dohrn also recognises the relationship of the *Merostomata* to the *Trilobites*, as shown especially by the development of *Limulus*, and considers that the three forms (*Limulidae*, *Eurypteridae*, and *Trilobite*) should be combined in one group under the name of *Gigantostreaca*, proposed by Haeckel, and placed besides the *Crustacea*. The author stated, on the authority of Prof. Owen, that *Limulus* really possesses two pairs of appendages which receive their nerves from the supraoesophageal ganglion; that, according to Dr. Packard, the young *Limulus* passes through a Nauplius-stage while in the egg; that no argument could be founded upon the lower lip, the condition of which varied extremely in the three groups proposed to be removed from the *Crustacea*; and he maintained that even from the ultra-Darwinian point of view taken by Dr. Dohrn, the adoption of his proposal would be fatal to the application of the hypothesis of evolution to the class *Crustacea*. Prof. T. Rupert Jones remarked upon the interest attaching to the study of the *Crustacea*, and called attention to the absence of any indications of convergence in our present knowledge of the class. He thought that, in the present day, we must nevertheless look back to some point of convergence from which the varied forms known to us may have pro-

ceeded by evolution. Prof. Macdonald remarked that difficulties must be expected to occur in classification. He believed that all Invertebrate animals were to be regarded as turned upon their backs, as compared with *Vertebrata*. The cephalic plate in *Limulus* he regarded as the equivalent of the palate-bone. The incisive palate was very distinct in the Crabs. The absence of one pair of antennae did not appear to be any reason for removing *Limulus* from the *Crustacea*. Dr. Murie considered that the contemplation of the multitude of young forms referred to by Mr. Woodward should serve as a warning to describers of species, and also as a check to generalisations as to the number of species occurring in various formations. He remarked that if we were at a point when the presence or absence of a single pair of nerves could be taken as distinguishing class from class, these classes must be regarded as very nearly allied. He thought that the doctrine of evolution was being pushed further than the known facts would warrant. Mr. Woodward, in replying, drew attention to the diagrams of the embryo and larva of the recent *Limulus*, comparing them with *Limulus* of the Coal-measures, *Neolimulus* of the Silurian, and also with the larval stages of the *Trilobites*, discovered by Barrande. He pointed out the strong resemblance which the fossil forms offer to the early stages of the modern King-crab, and expressed his assent to the proposal of Dr. Dohrn to bring the *Trilobita*, if possible, nearer to the *Merostomata*. If, however, the *Trilobites* have true walking-legs instead of mouth-feet (gnathopodites) only, they would be more closely related to the *Isoпода*. He showed by a tabular view of the *Arthropoda* that the known range in time of the great classes is nearly the same, and therefore affords no argument for combining the *Merostomata* with the *Arachnida*; but on the contrary, he considered that the *Trilobita* were, with the *Entomostreaca*, the earliest representatives of the class *Crustacea*, and could not therefore be removed from that class.—The following specimens were exhibited:—Specimens of Auriferous Quartz from New Caledonia, and of Tin Ore from New South Wales, exhibited by Mr. G. Milner Stephen; specimen of gold from the Thames Goldfield, New Zealand, exhibited by Prof. Tennant; specimens of *Eurypterus Scouleri* and of *Bellurinus* and *Prestwichia*, exhibited by the President; specimens of recent and fossil *Crustacea*, exhibited by Mr. H. Woodward, in illustration of his paper.

Zoological Society, January 2.—Mr. John Gould, F.R.S., in the chair. An abstract was read from a letter received from Mr. T. G. Riedel, of Gorontalo, Celebes, in reference to the true locality of a rare Kingfisher, *Tanyptera Riedeli*, which he stated to be from Kordo—an island in the Bay of Geelink, and not from Celebes.—Prof. Newton exhibited and made remarks on a specimen of Ross' Gull (*Larus Rossii*), from the collection of the late Sir William Milner, which was said to have been obtained in Yorkshire.—Mr. Gould exhibited an adult specimen of the same bird, from the Derby Museum, Liverpool.—Mr. P. L. Sclater read a paper on the species of monkeys found in America north of Panama, being supplementary to a former paper on the northern limit of the *Quadrumania* in the New World. The species of monkeys now ascertained to occur in Central America from Panama to Mexico were stated to be eleven in number—namely, ten belonging to the family *Cebidae*, and one to the *Hapalidae*. Full particulars were given concerning the range of each of these species.—Mr. Henry Adams communicated some further description of new species of shells, collected by Mr. R. McAndrew, in the Red Sea. A second paper by Mr. H. Adams contained descriptions of fourteen new species of land and marine shells from Mauritius, Mexico, Formosa, Borneo, and the New Hebrides.—Mr. George Gulliver communicated a paper on the oesophagus of a hornbill (*Tocicus melanoleucus*), being an appendix to a former paper by him on the taxonomic character of the muscular sheath of the oesophagus of the *Saurapsida*, read at a previous meeting of the Society.—Mr. J. Brazier communicated some observations on the distribution of certain species of volutes found in the Australian seas. In a second paper Mr. Brazier gave descriptions of six new species of land and marine shells from the Solomon Islands, Western Polynesia, and Australia.—Dr. J. C. Cox communicated descriptions of some new land shells from Australia and the South Sea Islands.

Entomological Society, January 1.—Mr. Alfred R. Wallace, president, in the chair.—The secretary read an extract from a letter received from Mr. Gould respecting the question of the liability of dragon-flies to the attacks of birds. Mr. Gould had no doubt that the hobby and kestrel attacked the larger kinds, and he had seen sparrows, &c., preying upon the smaller *Agriionidae*.—Mr. Müller called attention to a statement by

M. Emile Joly to the effect that Latreille's supposed crustacean genus, *Protopotoma*, is probably founded upon the immature condition of certain *Ephemeridae*.—Mr. Butler read a paper "On certain species of *Pericopidae*."—Mr. F. Smith read a letter from Mr. J. T. Meggidge with reference to the habits of some species of ants belonging to the genus *Aphentogaster*, as observed at Mentone in the winter. Mr. Meggidge affirmed that those ants harvested the seeds of various plants in chambers, sometimes excavated in solid rock. He had seen them busily engaged in conveying the seeds into these chambers, and found that, in most cases, the radicle was bitten off, so as to prevent germination; but he had also observed sprouted seeds being brought out again as apparently unfitted for store purposes. Many of the seeds had their contents extracted through a hole in one side, and though he had not actually seen the ants feeding upon them, he was inclined to believe that the stores were made for the purpose of providing food in the winter months.

Society of Biblical Archaeology, January 2.—Mr. S. Birch, president, in the chair.—A paper, entitled "Hebræo-Egyptian in Hebrew-Egyptian Analogues," contributed by M. François Chabas, Membre de l'Institut, and translated for the society by Mr. E. R. Hodges, was read by the translator. In this the learned Egyptologist, having enumerated the various sources and original texts from which his materials were taken, proceeded to consider the various moral and religious parallels of the Egyptians and Hebrews under three distinct sections: (1) Laws respecting charity and special duties; (2) Commands and proverbs enforcing the obligation of filial obedience; (3) Legal formulae and reports, referring to the prohibition of blasphemous and irregular oaths. Under each of the divisions several translations of hieroglyphic texts were given, together with an exegesis justifying the renderings adopted by M. Chabas. The last section, in which the adoration "by the life of God, and by the life of Pharaoh" was explained, possessed, in the opinion of the learned author, special interest from its exact attestation of the minute accuracy of certain portions of the Pentateuch, and as throwing much light upon a passage hitherto obscure or unknown to the bulk of English students.—The president read a paper "On the Cypriote Inscription on the Bronze Tablet of Idalium" (Dali). Having referred to the felicitous discovery, by Messrs. Lang and Smith, of the Cypriote alphabet, as announced to the society at its last meeting, he entered into the consideration of the Cypriote parts of the bi-lingual inscription of Dali, and the Hellenic element of the Cypriote language. He then proceeded to give some account of the Cypriote inscription on the bronze tablet of Dali, which records donations to the Temple of Idalium by the monarch, Pythagoras, and Indostes. It also referred to various writings in connection with a temple of Isis. Its date of inscription appears to be about B.C. 256. Examples were given of the Hellenic structure of the language, and the identification of many Cypriote with Greek words. An interesting discussion took place, in which Sir C. Nicholson, Emanuel Deutsch, Rev. J. M. Rodwell, S. M. Drach, W. R. A. Boyle, the president, and the secretary, took part.

EDINBURGH

Royal Physical Society, Dec. 20, 1871.—Mr. C. W. Peach, president, in the chair.—"Zoological Notes," by Prof. Duns. (1.) On a dog-fish (*Scyllium marmoratum*) from Java. (2.) On the Porbeagle, or Beumaris shark (*Lamna cornubica*). The specimen exhibited was a beautiful young one captured last year near Elie, Fifeshire. The difference between the dentition of the adult and the young was well illustrated in this case. The lanceolate teeth of the former have a small basal cusp on each side. The cusps are absent in the latter. (3.) On Rondel's little Sepia (*Sepioida Rondelleti*). A specimen taken in the Firth of Forth was exhibited. (4.) On the Redwing (*Turdus iliacus*).—On the Extirpation of Venomous Serpents from Islands, by Robert Brown. This consisted of correspondence addressed to the author and Mr. W. B. Tegetmeier relating to the subject. It was shown that the common domestic pig had exterminated rattlesnakes in the vicinity of the Dalles and other settlements in Oregon, and that in India the same antipathy is shown by the same animal to the deadly cobra di capello. The subject was important economically to the inhabitants of some of the West Indian Islands infested by these reptiles, and physiologically in so far as facts went to show that the pig enjoyed an immunity from the poison of both the rattlesnake and the cobra. In Ireland it was well known few or no snakes of any kind are found, and nowhere is "the pig" more abundant, showing a probable relation between these two facts, without calling in the supposed aid of St.

GLASGOW

Geological Society, December 14, 1871.—Mr. James Thomson, F.G.S., read a paper on "The Stratified Rocks of Islay." He described in detail the sedimentary deposits on the south side of the island, and then gave a transverse section of them from Port-na-Haven on the west to Port Askaig on the east. Although the rocks in the central valley of the island had not yet yielded identifiable organic remains, he did not despair, if properly investigated, of forms being found that would place them beyond doubt in the Lower Silurian series. In mineral character they quite coincided with those described by the late Sir Roderick Murchison as occurring in Ross and Sutherland-shires. On the east side of the island, at Port Askaig, these deposits repose upon a series of stratified rocks of much higher antiquity, which correspond to the Cambrian rocks of the North-West Highlands, described by the same distinguished author. At the base of these latter sedimentary rocks there is a mass of conglomerate, made up of fragments and boulders of granite, imbedded in an arenaceous talcose schist; and as no granite occurs *in situ* in the island, he was disposed to account for its presence in this conglomerate by the agency of ice. Specimens of the granite and a striated block of quartzite were laid upon the table. He then described the rocks of the western extremity of the island, which consist of highly metamorphosed stratified rocks, as gneiss, serpentine, dolomite, quartzite, and schists, extending from Port-na-Haven, on the west, to Brouch-Ladach, a distance of nine miles. At the latter point the superior deposits are seen resting on the metamorphosed sedimentary rocks, nearly at right angles to the planes of stratification. In lithological aspect and mineral character these rocks agreed so entirely with the "fundamental or Laurentian gneiss" of Sir R. Murchison, as occurring in the North-Western Highlands and other parts of the world, that he had not the slightest hesitation in placing them as belonging to this, the oldest division of known sedimentary rocks. It thus appeared that both Cambrian and Laurentian rocks occurred farther south in Scotland than had hitherto been recorded. Taking a general view of the group of deposits to which he had called attention, there were—1. The calcareous deposits in the central valley of the island, of Lower Silurian age; 2. The deposits from Ardnahamh on the north to Ballochreoch on the south, of Cambrian age; 3. The metamorphic rocks in the west of the island, of Laurentian age. He was not prepared to speak with any degree of certainty regarding the source of the materials constituting the basic conglomerate mass. These differ so widely from the granites found *in situ* in other parts of the Highlands, that he felt the necessity for tracing them to another source, and hoped he would not be thought to overstep the bounds of prudent speculation in suggesting that these erratics are the reassorted materials of some great northern continent that has yielded to the gnawing tooth of time, leaving only these scattered fragments to attest its former existence. The portion of striated rock which he had laid before the meeting pointed to an agency adequate to the transport of such materials, and indicated that we should have to contemplate a glacial period deeper in time than had hitherto been suspected, when glaciers and icebergs planed down the hardest rocks and dispersed their fragments, obedient to the same great laws which still regulate the economy of Nature.

NEW ZEALAND

Wellington Philosophical Society, August 26, 1871.—Capt. Hutton described the two species of bats found in New Zealand, and proposed that the name *Myotis tuberculatus* be changed to *M. velutinus*, to avoid confusion with *Scotophilus tuberculatus*. Dr. Hector mentioned that large numbers of the former species lodged in the topsails of H.M.S. *Clio* when in Milford Sound last summer.—Mr. Skey proposed as a convenient method of generating H₂S for laboratory use, to employ galena, zinc, and dilute hydrochloric acid.—Captain Hutton described the microscopic structure of the egg-shell of the moa, and showed that it was altogether different from the kiwi egg.

September 16.—Mr. W. T. L. Travers described the traditions of the Maories, showing reasons why they were not reliable as history, and that the usual date assigned for the first landing of the Maories is much too recent.—Captain Hutton read a paper on the lizards of New Zealand, and described a new species from

White Island, belonging to the genus *Norbea*, hitherto only found in Borneo, and also a new species, *Norbea laxa*.

September 30.—Mr. Travers described the habits of the birds that frequent the lake in the interior of Nelson, mentioning that the blue duck (*Hymenolaimus*) does not exhibit solicitude for the safety of its young like other ducks. Captain Hutton showed that this supported the Darwinian theory, as the blue duck belongs to a genus peculiar to New Zealand where there were no destructive animals previous to the arrival of man, and in which genus, therefore, instinctive fear has not been developed. Dr. Hector showed that absence of fear is characteristic of most of the birds peculiar to New Zealand, but that the weka of the North Island is much more shy than the species in the South.—Dr. Hector described a portion of a wreck discovered on the west coast of the Middle Island, and pointed out that the coast line had advanced 300 yards since it was cast up.

October 14.—A communication by Dr. Wojekof, of St. Petersburg, on the change of climate effected by clearing forests, led to much discussion, from which it appeared that this colony is now suffering in many districts from the sudden and severe floods that are due to this cause.—Captain Hutton read critical notes of the birds of New Zealand that accompany a descriptive catalogue he has published.

October 28.—Dr. Hector reported the result of Dr. Thomson's exploration of the cave in Otago in which the Moa's nest was found (see NATURE, vol. iv. pp. 184, 228). It is an irregular fissure in mica schist rock, about fifty feet deep, and with thin flat ledges or floors on which the bones rest. There are entrances, one from rocks on the mountain side, and the other by a funnel-shaped hollow in an alluvial flat. On the first floor Dr. Thomson found traces of a fire and charred bones. On the second floor, by scraping away the loose dust to the depth of two feet, leg bones, ribs, vertebrae, a pelvis, toe bones, tracheal rings, and pieces of skin and muscle were found. On the third floor were found fragments of egg-shell, and the bones of a bird with a keeled sternum. In Dr. Thomson's collection there are sixteen tibias, so that he obtained remains of at least eight birds. A perfect skull with lower jaw and trachea attached, and a femur with well preserved muscular tissues attached, were found on the spot where the nest was obtained. From another locality in the same district Dr. Thomson sends twenty feathers. These were found by a gold digger eighteen feet below the surface. A report on these feathers by Capt. Hutton showed that they were of the form peculiar to struthious birds, but quite different from any known species. They are eight inches long, with soft yellow down on the lower half, and black above except the tip, which is white. The form of the feather is very peculiar, as it expands in width to the tip. He considers that the structure of these feathers shows that the bird to which they belonged was allied more to the American robin than to any of the struthious birds of the old world.

VIENNA

I. R. Geological Institution, Dec. 5, 1871.—M. Ernest Favre exhibited a geological map of the central part of the Caucasus Mountain chain, which he had surveyed last summer. The region which formed the object of his inquiries is limited to the east by the military road which leads to Georgia, to the west it ends with the Elbrus Mountain, to the north it is limited by the Steppe, and to the south by the Koura Valley, the mountains of Souram and the plain of Mingrelia. In this region the Caucasus rises to its greatest height; summits of 12,000 to 18,000 feet above the sea level being not rare. Granite and crystalline slates form large masses in the central part, further to the east and west they disappear beneath the younger sedimentary rocks. The lowest fossiliferous strata belong to the Liassic formation. The gigantic peaks of the Elbrus and the Kaykeh on the north flank of the chain are formed by trachite.—Mr. F. Schröckenstein "On the Cyipka Balkan." The author has crossed the Balkan mountains in two lines, unvisited before by any geologist, once from Drawna by Selce to Kysanik, and than back over the Cyipka to Grabowa. The series of rocks found there he enumerates as follows:—1. Crystalline schists; 2. Coal formation, the base of which is formed by quartzite, higher up follows calcareous slate, and finally sandstone and slate with coal measures; 3. Dyas; 4. Magnesian limestone; and 5. The Neocomian series covering the older rocks unconformably. The discovery of large coal seams in the coal formation near Radencie is very important. German capitalists have got permission to work them, and have already traced a railway from the mine to the Danube.

THE SOLAR ECLIPSE

SURELY if eclipse expeditions had their mottoes, that of the expedition of this year should be *per mare per terram*; for it has been *per mare per terram* in our case with a vengeance! Probably when we return, the curious individuals who total up in the *Times* the aggregate number of years those people have lived whose deaths are there recorded, will, in asking us for our autographs, beg also a detailed statement of the number of miles each of us has travelled in the performance of our duty. I fear it will be very difficult to give the information; and if the temperature in the shade be wanted too, the thing will be perfectly hopeless; for, thank goodness, we took the precaution to bring no thermometers; had we done so and looked at them, it might have been all over with us. Let me point my remarks. A week ago I was at Bekul, having travelled I know not how many thousand miles by sea, and having scarcely set foot on land for a month. We were in the jungle, the heat was burning, some of us had fever, and it was opium which enabled me at all events to get through the eclipse, for it was that memorable day just a week ago. Since then, by night and by day, Dr. Thomson, Captain Maclear, and myself, have been—I seek a word, wafted is too weak, jolted is too strong, for some parts of our journey, though ridiculously lacking in expression for others—well, conveyed from Bekul, now in men-carried conveyances, the cunning bearers with their plaintive moaning, by no means unmelodious, keeping step, giving us an idea of the tremendous labour they were undergoing, and reminding us of a certain journey which we must all make once; now on men's shoulders, now in bullock bandy, speed about two miles an hour, thanks to a brutal breach of contract, which has upset my plans terribly, now in Indian railway carriages, average speed ten miles an hour, temperature of carriage at noon unknown, and lastly in the horse transit of the Madras Carrying Company. Oh! that their carriages were as good as their arrangements and the speed of their horses; and, now, here I am shivering, surrounded by hoar frost, with a soupçon of a difficulty of breathing in this higher air after the dense atmosphere of the jungles, but all the same in an earthly paradise with hedges of roses although it is mid-winter, the whole place a perfect garden. I am at Ootacamund, at an elevation of some 7,000 feet with an Australian fauna; and within a few hours I hope to see Janssen, who is still here; Tennant, Herschel, and Hennessy I have unfortunately missed, owing to the breach of contract already referred to.

We can all of us, or nearly all of us, afford to laugh now at any inconveniences we have suffered; for of the eleven who landed at Galle nine have seen the eclipse, some of us perhaps as an eclipse has never been seen before. Unfortunately, to the regret of all, Mr. Abbay and Mr. Friswell, who were among the best prepared for doing good work, and were at a station at which everybody said cloudless weather was certain, found themselves on the 12th in a storm of cloud and mist, which obscured the sun for, I believe, the whole day. With this exception

the telegrams from all the English parties have been sent regularly, while we have all been thankful to learn from the telegrams which Dr. Janssen and Colonel Tennant have had the great courtesy to send me, that they too saw the eclipse well, as also did Mr. Pogson, as I gather from the newspapers, but of course the details of their observations are still unknown to me. Hence, I can only give the facts observed by the party at Bekul and Poodocottah; Prof. Respighi, who observed at that station, having joined me at Pothanore, the station on the Madras Railway, at the foot of the hills which we ascended yesterday from 4.30 A.M. till 1 P.M.

But before I say a word about the observations themselves, it is incumbent upon me to express our deep obligations to the supreme Madras and Ceylon Governments for the magnificent manner in which they have aided us. Nothing could be more complete than the arrangements at Bekul made by the collector, Mr. Webster, and his assistant, Mr. Melvor, both for the work to be done and the comfort of those who had to do it. The same must be said for the Poodocottah party, where not only the collector, Mr. Whiteside, but the Rajah did everything in their power, the latter loading the observers with presents when they left. We have at present heard only of the discomforts of the Manantoddy party, and it is clear that here the local arrangements were in strong contrast to those elsewhere. The Ceylon parties, who parted from the main body at Galle, have doubtless been well looked after; as Captain Fyers, the Surveyor-General of the island, accompanied and aided them in their observations.

This brings us to another part of the arrangements. The Ceylon party had the unreserved use of the Government steamer the *Serendib*, to take them from Galle to their places of observation, Jaffna and Trincomalee, both on the coast, and the accommodation on board was perfect. The Indian parties proceeded to their various destinations, or the ports on the coast nearest to them, in the Admiral's flag-ship the *Glasgow*, which, however, could not remain to bring them back, a circumstance which has given rise to very considerable inconvenience and great risk for the instruments, which are now scattered all along the line, to be sent to the coast and from the coast to Bombay or Galle, as circumstances may determine. This of course was not to be helped, and we must hope for the best, especially as all the parties have done their utmost in superintending their repacking, and handing them over in perfect condition to the different Government officers who accompanied each party. Still, although it was not to be avoided, the withdrawal of the ship has been the unfortunate circumstance in the arrangements. Nothing could exceed the kindness of the Admiral, who vacated his own quarters to give us room, of Captain Jones, who took the warmest interest in our proceedings, and helped the arrangements greatly, and by the officers of the ship generally. Without the equal kindness of Mr. Webster at Bekul, the step from the Admiral's cabin into the jungle hut would have been a seven-league one.

As the mail, the first available one after the eclipse, leaves this place to-day, I must lose no more time in recording preliminaries. I will therefore at once state the general arrangements of the parties, and what I at

present know of the observations. The stations and observers as finally arranged were as follows :—

Bekul—Analysing Spectroscope, Capt. Maclear and Mr. Pringle.

Polariscope, Dr. Thomson.

Photography, Mr. Davis.

Manantoddy—Analysing Spectroscope, Mr. Friswell.

Integrating Spectroscope, Mr. Abbey.

Poodocottah—Spectroscope, Professor Respighi.

Sketches of Corona, Mr. Holiday.

Jaffna—Integrating Spectroscope, Capt. Fyers and Mr. Ferguson.

Polariscope, Capt. Tupman and Mr. Lewis.

Photography, Captain Hogg.

Trincomalee—Spectroscope, Mr. Moseley.

Besides these observers, we had at Bekul the valuable assistance of General Selby, commanding the troops in Canara and Malabar (for whose help in supplying guards' tents, &c., the friends of Science cannot be too thankful), Colonel Farewell, Judge Walhouse, and others, in sketching the Corona. At all stations, of course, most precious help in various ways was given by all present who volunteered for the various duties, though some of them lost a sight of the eclipse in consequence. Among those who helped in this way at Bekul were Mr. McIvor, Mr. Pringle, Captain Bailey who timed the eclipse, Mr. Cherry, and Captain Christie, the Inspector of Police, whose presence there turned out to be of the most serious value, for the natives seeing in the eclipse the great Monster Rahoo devouring one of their most sacred divinities, not only howled and moaned in the most tremendous manner, but set fire to the grass between our telescopes and the sun to propitiate the representative of the infernal gods. Captain Christie with his posse of police stopped this sacrifice at the right moment, and no harm was done.

Now for the observations. Perhaps I may be permitted to begin with my own, as at the present moment I know most about them. I determined to limit my spectroscopic observations to the spectrum of a streamer, and to Young's stratum, thereby liberating a number of seconds which would enable me to determine the structure of the undoubted corona with a large refractor, to observe the whole phenomena with the naked eye, and through a train of prisms with neither telescope nor collimator, and finally with a Savart and biquartz. I found the 120 seconds gave me ample time for all this, but owing to a defect in the counterpoising of my large reflector, which disturbed the rate of my clock, I missed the observation of the bright line stratum (assuming its existence) at the first contact. At the last contact Mr. Pringle watched for it and saw no lines.

Having missed this, I next took my look at the corona. It was as beautiful as it is possible to imagine anything to be. Strangely weird and unearthly did it look—that strange sign in the heavens! What impressed me most about it, in my momentary glance, was its serenity. I don't know why I should have got such an idea, but get it I did. There was nothing awful about it, or the landscape generally, for the air was dry and there was not a cloud. Hence there were no ghastly effects, due generally to the monochromatic lights which chase each other over the gloomy earth, no yellow clouds, no seas of blood—the great Indian Ocean almost bathed our feet—no death-

shadow cast on the faces of men. The whole eclipse was centred in the corona, and there it was, of the purest silvery whiteness. I did not want to see the prominences then, and I did not see them. I saw nothing but the star-like decoration, with its rays arranged almost symmetrically, three above and three below two dark spaces or rifts at the extremities of a horizontal diameter. The rays were built up of innumerable bright lines of different lengths, with more or less dark spaces between. Near the sun this structure was lost in the brightness of the central ring.

But from this exquisite sight I was compelled to tear myself after a second's gazing. I next tried the spectrum of a streamer above the point at which the sun had disappeared. I got a vivid hydrogen spectrum, with 1474 (I assume the point of this line from observation) slightly extended beyond it, but very faint throughout its length compared with what I had anticipated, and thickening downwards, like F. I was, however, astonished at the vividness of the C line, and of the continuous spectrum, for there was no prominence on the slit. I was above their habitat. The spectrum was undoubtedly the spectrum of glowing gas.

I next went to the polariscope, for which instrument I had got Mr. Becker to make me a very time-saving contrivance—a double eye-piece to a small telescope, one containing a Savart and the other a biquartz. In the Savart I saw lines vertical over everything—corona prominences, dark moon, and unoccupied sky. There was no mistake whatever about this observation, for I swept three times across and was astonished at their unbrokenness. I next tried the biquartz. In this I saw wedges, faintly coloured here and there; a yellowish one here, a brownish one there, with one of green on each side the junction, are all the colours I recollect. Then to the new attack—the simple train of prisms which, the readers of NATURE know, Professor Young had thought of as well as myself; its principle being that, in the case of particular rays given out by such a thing as the chromosphere, or the sodium vapour of a candle, we shall get images of the thing itself painted in that part of the spectrum which the ray inhabits, so to speak, we shall see an image for each ray, as if the prisms were not there. What I saw was four exquisite rings, with projections where the prominences were. In brightness, C came first, then F, then G, and last of all 1474! Further, the rings were nearly all the same thickness, certainly not more than 2' high, and they were all enveloped in a line of impure continuous spectrum.

I then returned to the finder of my telescope, a $3\frac{1}{4}$ inch, and studied the structure of the corona and prominences. One of the five prominences was admirably placed in the middle of the field, and I inspected it well. I was not only charmed with what I saw, but delighted to find that the open-slit method is quite competent to show us prominences well without any eclipse. I felt as if I knew the thing before me well, had hundreds of times seen its exact equivalent as well in London, and went on to the structure of the corona. Scarcely had I done so, however, when the signal was given at which it had been arranged that I was to do this in the 6-inch Greenwich refractor. In this instrument, to which I rushed, for Captain Bailey had just told us that we had "still 30 seconds more"—which I

heard mentally, though not with my ears, as "only 30 seconds more"—the structure of the corona was simply exquisite and strongly developed. I at once exclaimed, "like Orion!" Thousands of interlacing filaments varying in intensity were visible, in fact I saw an extension of the prominence-structure in cooler material. This died out somewhat suddenly some 5' or 6' from the sun, I could not determine the height precisely, and then there was nothing; the rays so definite to the eye had, I supposed, been drawn into nothingness by the power of the telescope; but the great fact was this, that close to the sun, and even for 5' or 6' away from the sun, there was nothing like a ray, or any trace of any radial structure whatever to be seen. While these observations were going on, the eclipse terminated for the others, but not for me. For nearly three minutes did the coronal structure impress itself on my retina, until at last it faded away in the rapidly increasing sunlight. I then returned to the Savart, and saw exactly what I had seen during the eclipse, the vertical lines were still visible!

Captain Maclear has promised to forward to you himself an account of his observations. I need only here therefore refer to their extreme value, adding what I should have stated before, that I saw the bright lines at the cusps, as he was so good as to draw my attention to them. I am however not prepared to say that they were visible through a large arc of retreating cusp.

Dr. Thomson confined his observations to the polariscope, using the Savart. He states that his observations were identical with my own.

Mr. Davis's photographic tent was below the cavalier in which our telescopes had been erected; and immediately after the observations I have recorded were over, I went down to see what success had attended his efforts. I was hailed when half-way there with the cheering intelligence "five fine photographs," and so they are, those taken at the beginning and end of the eclipse being wonderfully similar, with, I fancy, slight changes here and there; but on this point I speak with all reserve until they have been examined more carefully than the time at our disposal has permitted, and until they have been compared with those taken at Ootacamund, Avenashi, and, I hope, at Jaffna and Cape Sidmouth.

This exhausts the principal work done by the Bekul party, with the exception of the sketchers with General Selby at their head, who have recorded most marked changes in the form of the outer corona, and Mr. Webster, who was so good as to photograph the eclipse from a fort some eight miles away, with an ordinary camera, and obtained capital results.

Next a word about the Poodocottah, the other fortunate Indian party. Prof. Respighi has promised to send his results to you with this. About Mr. Holiday's labours I know nothing, except that he has obtained three sketches.

Concerning the Ceylon parties I give you a verbatim extract from the telegrams. From Jaffna: "Exceedingly strong radial polarisation, 35' above the prominences; corona undoubtedly solar to that height, and very probably to height of 50'." From Trincomalee Mr. Moseley informs me that he carefully watched for Young's bright line stratum, and did not see it, and that 1474 was observed higher than the other line.

This is the sum total of the information which has at

present reached me. It is clear there are discordances as well as agreements, the former being undoubtedly as valuable as the latter. It remains now to obtain particulars of all the observations of all the parties, before a final account can be rendered of the eclipsed sun of 1871. This, of course, will be a work of months; but if all goes well, I trust to obtain information shortly of the outlines of the work done by the Indian observers and M. Janssen, as I am now remaining in India for that purpose, and this I will communicate to NATURE by the earliest opportunity. In the meantime I hope the good people at home will think we have done our duty, and that all the members of the Government Eclipse Expedition of 1871 will soon be safely with them to give an account of their work.

J. NORMAN LOCKYER

Ootacamund, Dec. 19, 1871

CAPTAIN MACLEAR'S OBSERVATIONS

LONG before this, no doubt, you have heard of the success of the expedition, but you must be anxious to hear more of the details, and what the observations really were. When I last wrote to you from Point de Galle,* the expedition had arrived there on November 27th in the *Mirzapore*, and was about to proceed to the different stations selected. The Ceylon sections left on the 28th in the Colonial steamer *Serendib*, placed at our disposal by the Government. She was to leave Messrs. Moseley and Ferguson at Trincomalee, and then proceed to Jaffna, with Captain Fyers, R.E., Captain Tupman, R.M.A. and Mr. Moseley. We have since heard of the safe arrival of these gentlemen at their stations, and, by telegraph, of their successful observations on December 12th.

The Indian parties left Galle on the 28th in H.M.S. *Glasgow*, flag-ship of Admiral Cockburn, who kindly gave us his cabin accommodation. With a fair wind we made sail, and arrived at Bepore on the night of the 1st December. The next morning we landed Signor Respighi and Mr. Holiday to go by train to Poodocottah, and then we left for Cannanore where Messrs. Abbey and Friswell were disembarked to make their way across country to their station at Manantoddy. They had a troublesome and fatiguing journey to perform, with heavy instruments, which however they safely accomplished in three days, and we can only heartily regret that their labours were not recompensed by fine weather on the morning of the eclipse. At Cannanore we were fortunate enough to enlist the services of General Selby, commanding the troops; he came across to Bekul, and rendered good aid in making some valuable sketches of the corona during the eclipse.

We left Cannanore on the 3rd, and with the strong tide that sometimes runs up that coast, were only six hours in reaching Bekul. We found that Mr. Melvor, assistant collector, and Mr. Pringle, engineer, had arrived that morning from Mangalore, on the part of the Indian Government, had prepared the travellers' bungalow for our reception, and had cleared the keep of an old fort erected by Tippoo which would make a capital observatory. The bay is open and shelving, but there

* See NATURE, vol. v. p. 163.

was little surf, and on the morning of the 4th, instruments and all were safely landed and carried up to the fort.

Our voyage in the *Glasgow* had been uneventful; but I cannot take leave of her without speaking of the kindness and assistance we received from Captain Jones and all on board, and we were truly sorry that the duties of the station did not allow them to remain and give us that aid, which, with the interest that all took in the work, would have been so invaluable.

Bekul is an out-of-the-way place, twenty-five miles from Mangalore, from which place all our supplies had to be carried on the backs of coolies; this did not, however, prevent several gentlemen, interested in our proceedings, coming out to join us.

Our party consisted of four who came out from England, viz., Mr. Lockyer, Dr. Thomson, Mr. Davis, and Commander Maclear, besides Messrs. McIvor and Pringle, to whose foresight and care we are very much indebted for our success. It was further strengthened by Mr. Webster, collector at Mangalore, who took some valuable photographs during the eclipse, by General Selby from Cannanore, and several others, making our numbers up altogether to eighteen. Our bungalow was about a mile from the fort, of which the highest bastion in the inner rampart had been selected to mount the equatorials; it was in a most commanding position about eighty feet above the sea, and overlooking a vast extent of country. Just below us, in a well-sheltered spot, Mr. Davis fixed his camera and dark chamber.

The day of our landing the heat of the sun was terrible, and we had to wait till the cool of the afternoon before we could proceed to work. That night, however, a great advance was made, the bases of the equatorials were up, and all ready for the tubes, and a "chuppa," or awning of palm leaves erected to protect them from the night dews and midday sun. The next seven days were employed in getting our instruments perfectly adjusted and in practising with them. The weather left nothing to be desired, except that the sun would take his revenge out beforehand and strike down with such force as to render it impossible to work in the middle of the day. Only one morning was cloudy, and then not to an extent that would have interfered with observations. At night the stars shone with great brilliancy, and we had great delight in observing the clusters and nebulae, pity we could not have remained longer to make spectroscopic observations of the latter in such a clear atmosphere.

The morning of the 12th dawned bright and clear, only a few small clouds to be seen near the western horizon, a light breeze from the N.E. All were early at their stations watching anxiously the appearance of the sun, which rose over the distant hills about half-an-hour before the commencement of the eclipse. But now I shall speak only of my own observations; Mr. Lockyer has already given the account of those made by himself.

The instrument I used was a double equatorial of two 6-inch refractors mounted on the same base, one at either end of the declination axis. To one was attached a 6-prism spectroscope from Kew, lent by Mr. Spottiswoode, of great dispersive power. To the other was fixed a spindle bar, carrying an erecting eye-piece, and a 7-prism direct vision spectroscope, either of

which could be swung at pleasure into the focus of the object glass; the two tubes had been carefully made parallel, so that the same object was viewed in both telescopes. The 6-prism was worked nearly the whole of the time by myself, and the direct vision by Mr. Pringle, who had practised with it constantly during the last few days. I add the observations made by him. At the commencement of the eclipse the slit of the 6-prism was placed tangential to the point of contact, that of the direct vision radial, width such that the absorption lines were very distinct, but not too fine. No change was observed from the ordinary solar spectrum. Keeping the slit for the next quarter of an hour tangential to the northern cusp, C was very bright the whole length; F bright, but thin. The slit was then placed radial to the cusp, and four bright lines near C (besides C itself) became visible, one on the direct side within 10 units Kirchhoff, and three on the red side within 20 units, the length of all five varying, but not together the average being about $\frac{1}{3}$ the height the visible spectrum.

At 6h. 51m. M.T., twenty-five minutes after contact, on a large prominence, C lengthened to half height of spectrum; nine minutes afterwards cusp was at another prominence, the positions of these must have been about N. 13° , and nearly north.

At 7h. 8m. M.T. I watched with the direct vision radial and, besides the Hyd. and "near D" lines, observed another bright line a little more refrangible than the air band between δ and F. At 1830 Kirchhoff it was very faint, and soon disappeared; soon after this I saw F line double about the same height as usual, $\frac{1}{2}$ spectrum.

At 7h. 23m. M.T., having returned to the 6-prism radial to the cusp, I observed the Hyd. D, E and δ very plain; several lines then began to come into view, as near as I could judge all the iron lines from halfway between D and E to beyond δ . These kept on brightening and more lines coming in. I called Mr. Lockyer to look at the phenomenon, and we watched it together for two or three minutes until it became time to take position to observe totality. During these two or three minutes the cusp must have passed from about N. 38° E. to N. 70° E. or further, and the lines were not lost sight of till I moved the telescope and placed the slit tangential to the point where the light would disappear, keeping it there with R.A. movement. On looking through the spectroscope the field was full of bright lines, the light just enough to let me distinguish the positions from the well-known solar lines.

As totality came on the light decreased, and the lines increased exceedingly, rapidly in number and brightness, until it seemed as if every line in the solar spectrum was reversed; then they vanished, not instantly, but so quickly that I could not make out the order of their going, except that the Hyd. D, δ , and some others between D and δ , remained last. Then they vanished, and all was darkness. I then unclamped, and swept out right and left, but saw nothing; then went to the direct vision, but saw nothing; placed the telescope on the moon's limb by the eye-piece, then put in the spectroscope, but the light was not sufficient to show any spectrum; pointed the telescope carefully, first on the dark moon, and then on a bright part of the corona, but no spectrum. I then looked at the corona with the naked eye, saw a bright glory around the moon, stellar form, six-pointed, something like the nimbus

painted round a saint's head, extending to a diameter and a half. Looked through the finder, and saw the same form, but very much reduced in size and brilliancy; then examined with the 6in. and eye-piece, and saw nothing but a bright glow round the moon, not much more than the height of the big prominence plainly visible in the S.E. quarter. The last thirty seconds had now arrived, and, as previously arranged, Mr. Lockyer took my place at the 6in., while I again looked through the 6-prism spectroscopic to record anything that might be visible, but I saw nothing. As the spectroscopic was not on the sun's limb at the re-appearance of the light, I cannot state what took place.

During the remainder of the partial eclipse I watched the northern cusp as the moon uncovered the sun, and several times I saw distinctly the four bright lines near C; but saw nothing else worth recording.

The colour of the corona appeared to me a light pinkish white, very brilliant. I saw no streamers. The rest of the sky and everything around had a bluish tinge.

I will now give an extract from Mr. Pringle's report. He was observing with the direct-vision spectroscopic attached to the other 6-inch telescope, and with myself watching the northern cusp, slit radial:

"Until 6h. 47m. (mean time) bright lines C, near D, and F, of uniform brightness, and varying but slightly from normal height. At that time F brightened, C remained bright, line near D very faint. At 6h. 54m. all the lines lengthened to some four or five times their normal height, showing a prominence at the cusp. For the next ten minutes lines varying but little. At 7h. 4m. a large prominence at cusp; bright lines lengthening some eight or nine times their normal height. At 7h. 4m. 30s. a bright line appeared on the more refrangible side of F, and close to it, F lengthening considerably, and bending towards the red. All the before-mentioned lines were now bright, F longer than the rest, and remaining bent, the line near it being one-third its length. At 7h. 13m. observed three bright lines at δ , visible only at the extreme point of the cusp. Half a minute before totality, turned the slit tangential; but the slit not being exactly at the same place as that of Commander Maclear's, both refractors working by the same slow-motion screw [this was owing to the sway of the bars carrying the spectroscopic when it was being turned.—J. P. M.] I failed to obtain any results at the moment of totality. I then observed at the 6-prism just quitted by Commander Maclear, whilst that gentleman, observing at the direct-vision spectroscopic, swept out from the sun on one side, then brought the finder on the dark moon, and thence swept out from the sun on the opposite side. During this time nothing whatever was visible in the spectroscopic. I next observed with the naked eye: corona appeared radial, of a purplish white colour, brightest near the body of the moon; no very long rays perceptible. On holding the head sideways, rays of corona remained permanent, showing none to be due to defect of vision. Next observed corona through 2½" finder of refractor. Structure well-defined, wavy, nebulous, permanent. Remarkable a curiously-curved portion of corona, divided by a partial rift from an oblique ray. I should imagine the corona to extend about 7" beyond the sun, but did not accurately estimate the distance

whilst observing. When thirty seconds of totality remained, I went to finder of equatorial reflector; structure of corona not so apparent with higher power. Several prominences visible; one of large size, structure similar to that of corona. At about twelve seconds before end of totality, a perceptible brightening along the edge of the moon on the side of appearance; a few seconds before end of totality, I went to one prism corona spectroscopic attached to 7½" reflector. At the end of totality a considerable number of bright lines flashed in (what proportion of the whole I cannot say, perhaps a third). The line near D noticeably bright; continuous spectrum faintly visible a moment before the sun's limb showed. After totality observed at finder, the summit of a large prominence opposite the point of sun's re-appearance visible for several seconds after totality."

During the afternoon I tried to make an accurate sketch of the prominences on the sun's disc, but clouds came on, and I was prevented. It was not worth while keeping the instruments up another day for the purpose, so we commenced, and in two days they were safely packed for Bombay.

The rumours that our presence gave rise to among the natives were very amusing. First we heard that part of the sun was about to fall, and the wise men had come to the East to prevent it. Then when the formidable-looking instruments were seen mounted on the fort, they thought there was a war, and we were engineers going to put the fort in order to prevent a landing. This was strengthened by the fact that the *Glasgow* practised at a target before returning to Ceylon. This gave place to a flood about to descend, and all the Europeans were coming to the high ground to escape it.

When the eclipse commenced the usual shouting and beating of tom-toms went on, but a cordon of police prevented an invasion of the Observatory, and only a confused noise from below reached us.

MORSE ON TEREBRATULINA

The Early Stages of Terebratulina septentrionalis. By Edward S. Morse, Ph. D. (Boston Society of Natural History, vol. ii.)

MR. MORSE is one of the band of New England naturalists who have lately been making themselves known to us through that excellent periodical the *American Naturalist*, and who have shown themselves determined to take advantage of the opportunities offered to them by the presence on their sea-board of such zoological treasures as *Limulus* and *Lingula*. Mr. Morse obtained *Terebratulina* in abundance in the harbour of Eastport, Maine, and gives in this paper an account of the change in the form of the shell and the "arms" during development of this Brachiopod from a scarcely visible speck onwards. The changes are illustrated in two plates containing outline figures, and as far as Mr. Morse has observed consist firstly in the passage of the shell from a flat and shorter form to the elongated and convex shape with which we are familiar. Further, the

arms were found to commence as a series of ciliated tentacles placed around the mouth, and as nearly as possible identical with the lophophor of such a Polyzoon as *Pedicellina*. At first but six of these tentacles are seen; these increase in number, whilst the lophophor takes on its horse-shoe shape; and finally by the development of the free ends of the two sides of the horse-shoe the great Brachiopodian arms are produced. This is very interesting, and confirms *a priori* notions. At the same time we must dissent from the stress which Mr. Morse lays on the affinities of structure of Brachiopoda and Polyzoa, in so far as he wishes to separate these two widely from the Mollusca, and join them to a group which he calls Vermes. The Vermes have never been accurately defined, and are in fact at present, as Carl Gegenbaur (whom Mr. Morse cites) fully admits, one of those classificatory lumber-rooms, which are so convenient from time to time in the progress of zoological science. Whilst we fully admit the close affinities of the Polyzoa and the Brachiopoda—now long recognised by all zoologists—we cannot overlook the very strong affinities of these to the true Mollusca. Even a hasty study of the embryology of the Mollusca is sufficient to bring under one's eyes larval forms of various classes bearing many of the characteristics of the Polyzoa on the one hand, and of certain Vermes on the other. The early condition of the gill-plates in some Lamellibranchs is only to be compared to the tentacula of the Molluscoidan lophophor, though presenting so large a shifting in some relations. Rather than detach the Molluscoida (with regard to the Tunicata there are a variety of new facts and considerations which require long discussion) from the Mollusca to place them in the lumber-room Vermes—we should prefer to put the whole of the Mollusca along with them there—a proceeding at present useless, but which would express a truth which Mr. Morse does not seem to admit, though it is indicated by Gegenbaur, and accepted also by Huxley, namely, that there are close genetic ties between the group Mollusca (including Molluscoida), and certain so-called Vermes, such as the Turbellaria, Archi-annelida, &c.

In a paper published prior to this, Mr. Morse has spoken of the Brachiopoda as a division of Annelida, on the ground of certain resemblances between Lingula and Annelids. We are not sure whether Mr. Morse adheres to this startling proposition, or whether it was due to the intensity of the impressions produced by his study of living Lingula; which must have been exceedingly interesting. By the way, we may mention that Semper has also studied living Lingula. That there is a fundamental community of organisation between Lingula and Annelids we are, as stated above, not indisposed to believe, but that this can be expressed advantageously by making the Brachiopoda a division of Annelida, or that such a classification would be anything more than reactionary exaggeration, we cannot for a moment suppose. Mr. Morse attaches importance in this regard to the setæ of Lingula, and equal or perhaps more importance to the red colour of the blood. The discovery of red-coloured blood in Lingula is interesting, because in all probability it is due, as in vertebrates and all other causes where it is really red, to the presence of hæmoglobin, and is another instance of the exceptional appearance of this chemical principle in the blood of an animal whose nearest congeners do not

possess it. We should be very glad of confirmation with the spectroscope of the supposed existence of hæmoglobin in the blood of Lingula. But how can Mr. Morse suppose that this red blood, or hæmoglobin-bearing blood, is a character of the slightest classificatory importance? A great number of Annelids do not possess the vascular system at all, which in others carries this red blood; in some the fluid in that vascular system is coloured green by chlorocruorin, in others the hæmoglobin is present in the perivisceral fluid, which is in most Annelida colourless. Certain Mollusca have blood coloured red by hæmoglobin (Planorbis) as deeply and brightly as that of any lob-worm, so again have some Crustacea and Insect larvæ. The presence or absence therefore of hæmoglobin in the blood of Lingula is a matter of complete indifference as far as the relations of that animal to the Annelida are concerned.

We are much interested by a reference in Mr. Morse's paper on Terebratulina to some observations which he has made on the development of Lingula, observations which we hope before long to see published. From these he states that he is led to believe that the supposed Discina larva figured by Fritz Müller might equally as well be that of a Lingula. Some further information about this remarkable larval form will be very welcome.

Mr. Morse apologises for the undetailed character of his drawings, and for the absence of information in his paper upon the development of Terebratulina *ab ovo*—a great desideratum—by the fact that when he went to Eastport to study the development of Terebratulina he had a microscope with him which he found to be utterly inadequate to the purpose. Since this is an error which is easily remedied, we trust that Mr. Morse will soon return to the attack, if he has not yet already done so, duly armed.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

The Solar Eclipse

It does not happen more than once in a lifetime to see such a glorious and magnificent sight as that from which I have just returned; that is, the total eclipse of the sun. I have seen many eclipses before, but never anything to equal this. I was engaged to go with the Morgans to the top of the hill to see it. Got up at six, and found it a lovely morning; rode up to Morgan's, about half a mile, carrying with me glasses, smoked glass, and sun hat. Got there before seven, and found eclipse already begun. Got our two mirrors and watched the hole in the sun grow bigger and bigger. It began from the top, and we all went off to the highest point on the hill, from whence we could see all Ooly and the mountains round. When the eclipse got so far, the cold on the mountain grew much greater, the grass was so wet that no one's boots kept it out, the feet and hands grew cold, and with your back to the sun the light over the country was like twilight, or the earliest dawn. Gradually the lower streak got thinner and thinner, until at last there shone a light like the famous lime-light, and in a moment or two that went out and the sun was totally concealed; many stars were visible, the whole country looked dark—that is, half dark, like moonlight—the crows stopped cawing, and for two minutes and a half the total eclipse lasted, a sight I shall never forget, and then the lime-light again appeared at the bottom rim of the sun, and gradually more and more of him appeared, the crows began again at once, and the

cocks began to crow, the shadow now was inverted, and by degrees got smaller, until at nine o'clock the eclipse was over. I cannot but suppose that the scientific men must have had great opportunities of observation, and that to-day's pencil will carry home many a description. Anything more beautiful, more sublime, or more perfect, it would be impossible to conceive.

The Rigidity of the Earth

I HAVE been urged from several quarters to defend my argument for the rigidity of the earth against attacks which are supposed to have been made upon it. It has, in fact, never been attacked to my knowledge, and I feel under no obligation to defend it. There is, I believe, a general impression that grave objections to it have been raised by M. Delaunay, and it seems that even in this country some geological writers and teachers, in their reluctance to abandon the hypothesis of a thin solid crust, enclosing a wholly liquid mass, hastily concluded that all dynamical arguments against it had been utterly overthrown by Delaunay.

In point of fact Delaunay made no reference at all to the tidal argument, and clearly was unaware that I had brought it forward when he made his communication on the "Hypothesis of the interior fluidity of the terrestrial globe," to the French Academy, three years and a half ago, objecting to Hopkins's argument founded on precession and nutation, and merely quoting me as having expressed acquiescence. On this subject I say nothing at present, except that ten years ago, before I expressed (in my first communication of the tidal argument to the Royal Society) my assent to Hopkins's argument from precession and nutation, I had thought of the objection to this argument since brought forward by Delaunay, and had convinced myself of its invalidity. But I hope to be able on some future occasion to return to the subject, and to prove that any degree of viscosity, acting in the manner and to the effect described by Delaunay, must in an extremely short time abolish the distinction between summer and winter. My reason for writing to you at present is that I see in Mr. Scrope's beautiful book on Volcanoes (just published as a second edition) a sentence ("Prefatory Remarks," page 24), written on the supposition that the tidal argument had been brought forward for the first time at the recent meeting of the British Association in Edinburgh. I therefore take the liberty of suggesting to you that a reprint of the short abstract of my tidal argument, which appeared in the Proceedings of the Royal Society, for May 16, 1862, might not be inappropriate to your columns. I ought, however, to inform you that the tidal argument was carefully re-stated in the first volume of the treatise on Natural Philosophy, by Prof. Tait and myself, published in 1867, but as the volume is at present out of print, you may not consider this objection fatal to my proposal.

Glasgow University, Jan. 9

WILLIAM THOMSON

Abstract of Paper on the Rigidity of the Earth, by Prof. Sir William Thomson, F.R.S., received April 14, 1862

The author proves that unless the solid substance of the earth be on the whole of extremely rigid material, more rigid for instance than steel, it must yield under the tide-generating influence of sun and moon to such an extent as to very sensibly diminish the actual phenomena of the tides, and of precession and nutation. Results of a mathematical theory of the deformation of elastic spheroids, to be communicated to the Royal Society on an early occasion, are used to illustrate this subject. For instance, it is shown that a homogeneous incompressible elastic spheroid of the same mass and volume as the earth, would, if of the same rigidity as glass, yield about $\frac{1}{7}$, or if of the same rigidity as steel about $\frac{1}{2}$ of the extent that a perfectly fluid globe of the same density would yield to the lunar and solar tide-generating influence. The actual phenomena of tides (that is, the relative motions of a comparatively light liquid flowing over the outer surface of the solid substance of the earth), and the amounts of precession and nutation, would in one case be only $\frac{1}{7}$ and in the other $\frac{1}{2}$ of the amounts which a perfectly rigid spheroid of the same dimensions, of the same figure, the same homogeneous density, would exhibit in the same circumstances. The close agreement with the results of observation presented by the theory of precession and nutation, always hitherto worked out on the supposition that

the solid parts of the earth are perfectly rigid, renders it scarcely possible to admit that there can be any such discrepancy between them as 3 to 5, and therefore almost necessary to conclude that the earth is on the whole much more rigid than steel. But to make an accurate comparison between theory and observation, as to precession, it is necessary to know the absolute amount of the moment of inertia about some diameter; and from this we are prevented by the ignorance in which we must always be as to the actual law of density in the interior. Hence the author anticipates that the actual deformation of the solid earth by the lunar and solar influence may be more decisively tested by observing the lunar fortnightly and the solar half-yearly tides.* These tides, it may be supposed, will follow very closely the "equilibrium theory" of Daniel Bernoulli for all oceanic stations, and the author suggests Iceland and Teneriffe as two stations well adapted for the differential observations that would be required.

The earth's upper crust is possibly on the whole as rigid as glass, more probably less than more. But even the imperfect data for judging referred to above render it certain that the earth as a whole must be far more rigid than glass, and probably even more rigid than steel. Hence the interior must be on the whole more rigid, probably many times more rigid, than the upper crust. This is just what, if the whole interior of the earth is solid, might be expected when the enormous pressure in the interior is considered, but it is utterly inconsistent with the hypothesis held by so many geologists that the earth is a mass of melted matter enclosed in a solid shell of only from 30 to 100 miles' thickness. Hence the investigations now brought forward confirm the conclusions arrived at by Mr. Hopkins, that the solid crust of the earth cannot be less than 800 miles thick. The author indeed believes it to be extremely improbable that any crust thinner than 2,000 or 2,500 could maintain its figure with sufficient rigidity against the tide-generating forces of the sun and moon, to allow the phenomena of the ocean tides and of precession and nutation to be as they are.

Extract from Thomson and Tait's "Natural Philosophy."

"§832. . . . All dynamical investigations (whether "static or kinetic) of tidal phenomena, and of precession and "nutation, hitherto published, with the exception referred to "below, have assumed that the outer surface of the solid earth "is absolutely yielding. A few years ago, for the first time, "the question was raised: Does the earth retain its figure with "practically perfect rigidity, or does it yield sensibly to the de- "forming tendency of the moon's and sun's attractions on its "upper strata and interior mass? It must yield to some extent, "as no substance is infinitely rigid. But whether these solid "tides are sufficient to be discoverable by any kind of observa- "tion, direct or indirect, has not yet been ascertained. The "negative result of attempts to trace their influence on ocean "and lake tides, as hitherto observed, and on precession and "nutation, suffices, as we shall see, to disprove the hypothesis "hitherto so prevalent, that we live on a mere thin shell of solid "substance enclosing a fluid mass of melted rocks or metals, "and proves, on the contrary, that the earth is much more rigid "than any of the rocks that constitute its upper crust."

"§833. The character of the deforming influence will be "understood readily by considering that if the whole earth were "perfectly fluid, its bounding surface would coincide with an "equipotential surface relatively to the attraction of its own "mass, the centrifugal force of its rotation and the tide generat- "ing resultant of the moon's and sun's forces, and their kinetic "reactions. Thus there would be the full equilibrium lunar and "solar tides; of 21 times the amount of the disturbing deviation "of level if the fluid were homogeneous, or of nearly twice "this amount if it were heterogeneous with Laplace's hypotheti- "cal law of increasing density. If now a very thin layer of "lighter liquid were added, this layer would rest covering the "previous bounding surface to very nearly equal depth all round, "and would simply rise and fall with that surface, showing only "infinitesimal variations in its own depth, under tidal influences. "Hence had the solid part of the earth so little rigidity as to "allow it to yield in its own figure very nearly as much as if it were "fluid, there would be very nearly nothing of what we call tides "—that is to say, rise and fall of the sea relatively to the land; "but sea and land together would rise and fall a few feet every

† Communicated August 22, 1862, and read November 27, of same year.

‡ *Dynamical Problems regarding Elastic Spheroidal Shells and Spheroids, of Incompressible Liquids.*

* High tide, as far as the influence of either body is concerned, is produced at the poles, and low water at the equator, when its declination, whether north or south, is greatest, and low water at the poles and high water at the equator, when the disturbing body crosses the plane of the equator.

"twelve lunar hours. This would, as we shall see, be the case if the geological hypothesis of a thin crust were true. The actual phenomena of tides, therefore, give a secure contradiction to that hypothesis. We shall see, indeed, presently, that even a continuous solid globe of the same mass and diameter as the earth, would, if homogeneous and of the same rigidity as glass or as steel, yield in its shape to the tidal influences three-fifths as much or one-third as much as a perfectly fluid globe; and further, it will be proved that the effect of such yielding in the solid, according as its supposed rigidity is that of glass or that of steel, would be to reduce the tides to about $\frac{2}{3}$ or $\frac{1}{3}$ of what they would be if the rigidity were infinite."

"§ 834. To prove this, and to illustrate this question of elastic tides in the solid earth, we shall work out explicitly the solution of the general problem of § 696 for the case of a homogeneous elastic solid sphere exposed to no surface traction; but deformed infinitesimally by an equilibrating system of forces acting *bodily* through the interior, which we shall ultimately make to agree with the tide generating influence of the moon and sun."

"§ 847. We intend in our second volume to give a dynamical investigation of precession and nutation, in which it will be proved that the earth's elastic yielding influences these phenomena in the same proportionate degree as it influences the tides. We have seen already that the only datum wanted for a comparison between their observed amounts and their theoretical amounts on the hypothesis of perfect rigidity, to an accuracy of within one per cent., is a knowledge of the earth's moment of inertia about any diameter within one per cent. We have seen that the best theoretical estimates of precession hitherto made, are in remarkable accordance with the observed amount. But it is not at all improbable that better founded estimates of the earth's moment of inertia, and more accurate knowledge than we yet have from observation, of the harmonic of the second degree in the expression of external gravity, may show that the true amount of precession (which is known at present with extreme accuracy) is somewhat smaller than it would be if the rigidity were infinite. Such a discrepancy, if genuine, could only be explained by some small amount of deformation experienced by the solid parts of the earth under lunar and solar influence. The agreement between theory on the hypothesis of perfect rigidity, and observation as to precession and nutation, are, however, on the whole so close as to allow us to infer that the earth's elastic yielding to the disturbing influence of the sun and moon is very small—much smaller, for instance, than it would be if its effective rigidity were no more than the rigidity of steel."

"§ 848. It is interesting to remark that the popular geological hypothesis, that the earth is a thin shell of solid material, having a hollow space within it filled with liquid, involves two effects of deviation from perfect rigidity, which could influence in opposite ways the amount of precession. The comparatively easy yielding of the shell must, as we shall see in our second volume, render the effective moving couple, due to sun and moon, much smaller than it would be if the whole interior were solid, and on this account must tend to diminish the amount of precession and nutation. But the effective moment of inertia of a thin solid shell containing fluid, whether homogeneous or heterogeneous, in its interior, would be much less than that of the whole mass if solid throughout; and the tendency would be to much greater amounts of precession and nutation on this account. It seems excessively improbable that the defect of moment of inertia due to fluid in the earth's interior, should bear at all approximately the same ratio to the whole moment of inertia, that the actual elastic yielding bears to the perfectly easy yielding which would take place if the earth were quite fluid. But we must either admit this supposition, improbable as it seems, or conclude (from the close agreement of precession and nutation with what they would be if the earth were perfectly rigid) that the defect of moment of inertia, owing to fluid in the interior, is small in comparison with the whole amount of inertia of the earth about any diameter; and that the deformation experienced by the earth from lunar and solar influence is small in comparison with what it would be if the earth were perfectly fluid. It is, however, certain that there is some fluid matter in the interior of the earth; witness eruptions of lava from volcanoes. But this is probably quite local, as has been urged by Mr. Hopkins, who first adduced the phenomena of precession and nutation to disprove the hypothesis that the solid part of the earth's mass is merely a thin shell."

The Kiltorcan Fossils

I HAVE just seen Mr. Carruthers' letter in your number of January 4th, to which I beg leave to reply.

In this communication it now appears that Mr. Carruthers' former remarks in the discussion upon Prof. Heer's paper were intended as a personal attack upon me; as he now states that on me alone rests the credit of misleading Prof. Heer by my erroneous determination of the Kiltorcan plant.

I have no hesitation in acknowledging to having referred the Kiltorcan plant in question to *Sagenaria veltheimiana*, and I think it very possible I may even now be correct. I will however now state the reason for my afterwards adopting Professor Schimper's name in preference. When that gentleman was in Ireland he spent some time in the examination of the Kiltorcan fossils, and did not then object to my determination of the species; it was afterwards, on my sending him a collection, that his further study of these fossils and comparison with the original species (of which I had only seen figures) enabled him to announce to me what he believed to be the distinctive characters in relation to the fruit which accompanied it, of those I had named *Sagenaria veltheimiana*; these fossils in his letter to me he referred to *Sagenaria*, and afterwards in his work "Traité Paléontologie Végétale," to *Knorria* under the name of *K. bailyana*. In the meantime I had read my report on these fossils at the British Association, and naturally adopted the generic name first applied to it by Prof. Schimper, which I afterwards corrected to *Knorria*, on his authority, in my "Figures of British Fossils," as Mr. Carruthers states.

In my letter to Professor Heer (June 1870) accompanying the specimens which I was requested to send him for his comparison with the Bear Island flora, I named those from Kiltorcan *Sagenaria bailyana* in accordance with Prof. Schimper's determination, whilst others from Tallow Bridge, co. Waterford, which he specially wished to see, I still referred to *S. veltheimiana*. I made him aware of Prof. Schimper's views on these plants, stating distinctly that they were originally referred by me to *S. veltheimiana*, but that Prof. Schimper, in consequence of his being enabled to compare the fruit accompanying it with that of the true *S. veltheimiana*, had arrived at the conclusion that it could not be that species, and therefore he had named it as a distinct one. Under these circumstances I cannot see how Mr. Carruthers can charge me with misleading Prof. Heer, who had the whole facts, with examples of the specimens from both localities, to draw his own conclusions from; with his acknowledged powers of discrimination, surely he was fully competent to judge for himself as to their correct identity.

The amount of Mr. Carruthers' knowledge on the subject about which he writes, is evidenced from his intimation that the fossil figured by me in the explanation to Sheet 187, &c., of the Irish Survey maps, is from Kiltorcan (co. Kilkenny), whereas it was sketched by me, on the spot, at Tallow Bridge (co. Waterford), where the section exposed exhibited a profusion of these plants in various conditions and stages of growth. The character of the rock in which they occur is totally different from that at Kiltorcan, the former being a grey shale, corresponding with the Lower Carboniferous shales, the latter a fine-grained greenish sandstone; neither has any of the associated Kiltorcan fossils, including the fish which are of typical Devonian or Old Red sandstone genera, ever been found at Tallow Bridge. I did however state in this memoir my belief that the *S. veltheimiana*, as identified by me at Tallow Bridge, was similar to the Kiltorcan plant in question, and also that it corresponded with the so-called *Knorria* of the Marwood beds, N. Devon.

With reference to Mr. Carruthers' announcement that *Sagenaria veltheimiana* is a "coal measure plant," I may remark that it is a particularly abundant fossil, occurring in various conditions, but seldom, if ever, met with in the typical coal series of Great Britain; I have identified it from the sandstones of the lower coal measures in the North of Ireland, as well as at various localities in the Lower Carboniferous shales of the Counties of Cork and Kerry. On the Continent, especially in Germany, it appears to be still more universal, and has been recorded under various names by fossil botanists, as Dr. H. K. Goepfert, in his "Fossile Flora der Silurischen der Devonischen," &c., mentions more than twenty synonyms for this species; moreover the same author states its occurrence to be "In der Kulmgrauwacke, dem Kohlenkalke und in der jüngsten Grauwacke." Dr. F. Unger and Dr. H. B. Geinitz, the latter of whom personally inspected the collections from Kiltorcan and Tallow Bridge, also mentions similar lower geological horizons at which it occurs; and Dr.

W. P. Schimper in the work before cited places it in Lepidodendron as a characteristic plant "des formations houillères inférieures (grauwacke culm) correspondant au calcaire carbonifère." It is therefore evidently more characteristic of the Lowest Carboniferous than of the coal measures; the older of these formations being considered by Sir Charles Lyell "as equivalents of the Lower Carboniferous, and were even formerly referred to the Devonian group."

I believe enough has now been said to show the part I took in misleading this eminent Professor, and I will leave those interested to judge between the merits of Mr. Carruthers' or Prof. Heers' classification, but in conclusion I must request to be allowed to state that prior to this gentleman's accusation against me, he made me a proposal to help him out of his controversy with Prof. Heer, and to "join him in a memoir to describe and figure the valuable materials I had collected;" this I had to decline, because it would not only have interfered with my official duties, but might also have drawn me into a discussion in which I had no interest, besides the probability of its committing me to what may prove to be erroneous opinions.

Circumpolar Lands

IN NATURE of December 28 there is an interesting letter endeavouring to show that the land everywhere about the North Pole down to lat. 57° is rising. We know less about the South Pole regions, but there are active volcanoes in the Antarctic Continent, and Darwin has shown in his work on volcanic islands that the land and sea-bottom are rising. This appears to be at least a remarkable coincidence.

The earth must be cooling by the escape of the central heat in volcanic eruptions and hot springs, and by slow upward conduction through the strata. As it cools it must contract. Can any mathematical reason be assigned why the contraction should be least in the direction of the polar diameter? This would account for the rising of the land at the poles.

J. J. MURPHY

English Rainfall

IN NATURE of the 11th inst. your reviewer, "J. K. L." (p. 201), makes a mistake in stating that the greatest English rainfall takes place at Cockley Bridge, Seathwaite. The greatest fall takes place at the Styte and on the north side of Styte Head, Seathwaite, Borrowdale; whereas the Cockley Bridge named by your reviewer is Seathwaite, Valley of the Duddon, and many miles from the place of greatest fall. He has evidently confounded the two Seathwaites. A reference to Mr. J. G. Symons' annual rainfall returns will show that the Seathwaite named is the one in Borrowdale.

G. V. VERNON

Wanted, a Government Analyst

I AM a grocer in a small way in a country place, so that I retail almost all that comes under the name of food; and I am very desirous that all should be unadulterated and worth its price, as far as a fair profit will allow. But how am I to ensure this, even supposing I possessed the requisite knowledge and appliances? Time would be wanting to carry out a systematic analysis, and the ordinary "rule of thumb" tests are not a match for the increasing cleverness of "manufacturing chemists." It only remains to send samples to some known food analyst; but here the expense becomes a barrier, when the dealings dependent on it are on a small scale. Is there (or, if not, ought there not to be?) some Government functionary to whom samples could be sent for testing, at a charge to just cover necessary expenses? After reading a very sad article on "Artificial Milk," in your paper of Dec. 15, I feel emboldened to ask whether, either of yourself or through any of your readers, you could assist me to render practical a feeling I am sure you must sympathise with. For obvious reasons, I ask you to receive in strict confidence the name and address I have given to show the genuine nature of my application.

GROECR

Earthquakes in Celebes

I WISH to contribute to the list of earthquakes and eruptions in your journal the following, all of which I have witnessed:—

- 1871
May 1 . Eruption of a volcano on the Island Camiguin, south of the Philippine Islands.
June 13 . Earthquake in Kakas, at the Lake of Tondano in Minahassa, North Celebes, 7½ P.M. This shock was at the same time felt throughout Minahassa.
July 15 . Earthquake at Gorontalo, North Celebes, Bay of Tomini, 12½ P.M. and 10½ P.M.
" 19 . Earthquake at Gorontalo, 12 A.M., heavy.
August 7 . Eruption of the volcano of Ternate. This eruption had not ended August 23. Most of the inhabitants of Ternate ran away. Stones and ashes were thrown as far as Halmahera.
" 19 . Earthquake at Gorontalo, 5 A.M.
" 25 . Scaquake at Gorontalo, 3 P.M.
" 31 . Earthquake at Gorontalo, 1 P.M., very strong, vertically.

In the month of August there were at Gorontalo a series of earthquakes, all of which I did not notice in my diary, some of them very severe, shocks so severe and numerous have not been experienced for years at that place. I do not doubt that they were in connection with the long-continued eruption of the volcano of Ternate in the same month.

Some years ago there was communicated to the Paris Academy, from South America, the fact that permanent magnets lose their magnetism during earthquakes. I will not discuss here the theoretical point of view of the question. During my whole stay in the northern part of Celebes I have always hung up a magnet, with a maximum weight attached to it, but never, not even during the severe earthquakes of Gorontalo, has the weight fallen down. I therefore doubt the fact.

Earthquakes are felt throughout the northern part of Celebes, on the coasts of the Bay of Tomini, at the Togan Islands in the Bay of Tomini; whereas in the southern part of Celebes, for instance at Macassar, earthquakes are scarcely ever felt or only very slight ones. The geological structure of the southern part of Celebes differs entirely from that of the northern.

I enclose a list of earthquakes observed at Gorontalo from 1866-70 by Mr. Riedel.

List of earthquakes at Gorontalo (N. lat. 0° 29' 42", W. long. 23° 2' 50") between the year 1866 and 1870:—

Year.	Month.	Day.	Hour.	Direction.	Direction of the Wind.
1866	February	18	1 p.m.	E.—W.	N.W.
	April	5	7½ p.m.	—	E.S.E.
	April	6	10½ a.m.	E.—W.	—
	June	20	6½ a.m.	E.—W.	E.S.E.
	September	5	8½ a.m.	—	S.E.
1867	December	2	3½ p.m.	E.—W.	W.
	February	26	11½ p.m.	E.—W.	W.
	March	22	4½ p.m.	—	N.W.
	March	30	9 p.m.	—	—
	April	22	10 a.m.	E.—W.	N.W.
	May	17	3 p.m.	E.—W.	S.E.
	June	26	8½ p.m.	E.—W.	S.E.
	July	26	8 a.m.	—	S.E.
	August	27	2 a.m.	E.—W.	S.E.
	September	14	10½ p.m.	E.—W.	S.E.
1868	December	23	10 p.m.	E.—W.	W.
	April	7	9½ p.m.	E.—W.	W.N.W.
	May	27	6½ p.m.	E.—W.	S.S.E.
	June	13	9½ p.m.	E.—W.	S.S.E.
	July	27	11½ a.m.	E.—W.	S.E.
	September	4	9½ p.m.	—	S.E.
	November	18	6½ a.m.	E.—W.	S.E.
1869	March	3	10½ a.m.	E.—W.	S.E.
	May	3	7 p.m.	E.—W.	N.W.
	August	22	9½ p.m.	E.—W.	S.E.
	November	17	4½ p.m.	E.—W.	W.N.W.
1870	April	7	12½ a.m.	E.—W.	W.S.W.
	July	12	5½ a.m.	E.—W.	W.S.W.
	August	28	3½ a.m.	E.—W.	W.S.W.

I am now going to the southern parts of the Philippine Islands, and in the following year to New Guinea. A short communication of my travels in Celebes will be found in *Petermann's Geographische Mittheilungen*.

Macassar, Celebes, Nov. 10, 1871

A. B. MEYER

ELECTROPHYSIOLOGICA :

SHOWING HOW ELECTRICITY MAY DO MUCH OF WHAT IS COMMONLY BELIEVED TO BE THE SPECIAL WORK OF A VITAL PRINCIPLE.

III.

2. *In continuation of the question—How in muscular action electricity may do much of what is commonly believed to be the work of a vital principle.*

CONNECTED with the history of electrotonus as exhibited in these experiments* are also other facts which must not be overlooked in this attempt to trace out the workings of electricity in muscular action—facts which show that the departure of contractility and the arrival of rigor mortis are considerably retarded by both forms of electrotonus. Left to itself, the gastrocnemius of the frog loses its contractility and passes into the state of rigor mortis in a time varying with the season and from other causes from 6 to 12 hours; but not so when left to the action of electrotonus. In this latter case, indeed, the contractility may remain for 18, 24, or 36 hours—for a longer time in anelectrotonus than in cathelectrotonus—and even then there may still be no signs of rigor mortis. Once, where anelectrotonus was kept up steadily all the time, and where contractility lingered for 36 hours, the muscles were still limber at the end of 48 hours. No doubt, before exact conclusions can be drawn in these matters more experiments are wanted, many more; but it is not necessary to wait for these in order to be certain that the departure of contractility, and the arrival of rigor mortis, are considerably retarded by the action of both forms of electrotonus. And it is simply to the bare fact that attention is now directed.

What then? Do these facts bear upon what has gone before, and, if so, how?

The facts are obvious. In anelectrotonus and cathelectrotonus alike there are—suspension of the tetanus caused by feeble faradaic currents, elongation of muscle, exalted contractility, together with considerable retardation in the time at which contractility passes off and rigor mortis comes on. In anelectrotonus and cathelectrotonus the parts, muscle and nerve alike, are charged with a charge larger in amount than that which is natural to them—a positive charge in anelectrotonus, a negative in cathelectrotonus. The facts, indeed, are strangely in keeping with the premises. Only let it be supposed that the artificial charge acts upon the dielectric sheaths of the fibres as the natural charge has been supposed to act, but in the contrary direction, that is from without to within instead of from within to without, the charge imparted to the outside inducing the opposite charge on the inside, and all the rest follows. The artificial charge is larger in amount than the mutual charge, and hence the increased elongation of the muscular fibres, the compression arising from the natural attraction of the two opposite elements of the charge keeping up a state of elongation proportionate to the amount of the charge. Hence, also, the suspension of the tetanus by electrotonus, for if the charge elongates the fibres it is easy to see that another of its actions may be that of suspending or antagonising muscular action. And hence again the increased contractility, for, according to the premises, contraction, happening under these circumstances, will be greater because the elasticity of the muscle has freer play at the discharge. In these matters the artificial charge plays the same part as the natural charge, only more energetically, nothing more. And not less so, as it would seem, in the action exercised upon the passing off of contractility and coming on of rigor mortis. Contractility passes off and rigor mortis comes on in the ordinary course of things, because the muscle loses its natural electricity. Contractility passes off and rigor mortis

comes on more slowly in electrotonus because the artificial charge associated with this state can take the place and do the work of the natural charge. This is all. Indeed, so far, the whole electrical history of muscle would seem to point to the view which led to the experiment with the elastic band, and to show that living muscle is kept in a state of elongation by the presence of an electrical charge, and that contraction is nothing more than the action of the fibres, by virtue of their elasticity, when liberated by discharge from the charge which kept them elongated previously—ordinary muscular contraction differing from rigor mortis in this only, that the charge which prevents contraction is suddenly withdrawn, and immediately replaced, in the former case, and gradually withdrawn, and not replaced, in the latter case.

Upon this view, also, it is possible to get a glimpse of the reason why contraction is more antagonised by anelectrotonus than by cathelectrotonus; and why contractility is slower in passing off, and rigor mortis slower in coming on, under the former state than under the latter. In anelectrotonus the artificial charge of the parts, muscle and nerve alike, is positive, and, being so, the sheaths are positive externally, and (by induction) negative internally, the manner of charging, which, there is reason to believe, is natural to the muscle. In cathelectrotonus, on the other hand, the opposite state of things obtains. Here the artificial charge is negative, not positive. Here, consequently, the charging of the sheaths is negative on the outside and positive on the inside—a state of things which is not natural to the fibres, or which is only met with exceptionally, when these fibres are upon the point of passing into the state of rigor mortis. In anelectrotonus, therefore, the natural charge may co-operate with the artificial charge in a way in which it cannot do in cathelectrotonus; and which, without further comment, it is easy to see may explain in some degree why contraction is more antagonised by anelectrotonus than by cathelectrotonus; and why contractility passes off and rigor mortis comes on more slowly under the former condition than under the latter.

As I have shown elsewhere,* the whole electrical history of muscle is in keeping with this view. The charges obtained from the common friction machine act in the same way as those associated with electrotonus. Everywhere, the question is not of polarisation and of changes in direction of a continuous current, but simply of charge and discharge. Everywhere it is charge preventing, and discharge permitting, action. In a word, the whole electrical history of muscle would seem to show that electricity may have much to do in what is commonly believed to be the work of contractility and tonicity, and that the way in which this work is done is that which is here pointed out.

Against this view, however, sundry objections may be urged. It may be said that the phenomena of muscular action in muscles with sheathed fibres cannot be explained after this fashion. It may be said that the proof of charge during rest and discharge during action is little more than a matter of imagination. It may be said that the force of the natural electricity of muscle is inadequate as force. But, in reality, these objections, when fairly looked into, prove to be of little value.

No doubt the fibres of involuntary muscles differ from those of voluntary muscles in having no proper sheaths. Instead of having those sheaths, indeed, they are made up of cells, mostly fusiform in shape, imbedded in a sort of homogeneous plasma or matrix; and these cells, there is reason to believe, are the contractile elements of the fibres. Still it is not easy to allow the force of any objection arising in this fact, for may it not be that the walls of these contractile cells, which, like the sheaths of the fibres of voluntary muscle, in the main consist of the material of elastic tissue, behave in the way the sheath is supposed to behave under the charge and discharge, that a charge developed on the

inside of these walls induces the opposite charge on the outside, that the walls elongate under the compression arising from the mutual attraction of these charges, and shorten when this charge is discharged, because their elasticity is then left free to come into play? Nay, may it not be that this action of the cell membrane is not excluded in those long voluntary muscles in which the fibres seem to be made up of several cells or fibres over-wrapping at their ends, rather than of a single sheathed fibre? And, certainly, this idea is not contradicted by facts remaining in the background; for, as will be seen in due time, these go to show that the walls of all cells and fibres are affected electrically in the same way as that in which the sheath of the fibre of voluntary muscle is supposed to be affected. So that, after all, the phenomena of rest and action in sheathless muscular fibres may supply no valid objection to the view which has been taken of these phenomena as presented in muscular fibres with proper sheaths.

And surely the evidence supplied by the new quadrant electrometer is a sufficient contradiction to the objection that the charge during muscular rest and the discharge during muscular action are mere matters of imagination, for this evidence shows unequivocally that there is a charge during this state of rest and a discharge during this state of action. It is not a question of inference merely, such as it might be if the evidence supplied by the galvanometer were alone available; for here, as has been pointed out, the current during rest, and the comparative disappearance of this current during action, may in reality point to charge and discharge when traced to their causes: it is a question of simple fact. Moreover, the anatomical and physiological analogies existing between the muscular apparatus and the electrical apparatus in the torpedo and the phenomena of secondary contraction, make it more than probable that muscular action is accompanied by a discharge analogous to that of the torpedo. Like the nerves of the muscle, the nerves of the electric organs originate in the same track of the spinal cord, and terminate in the same manner. Like the muscles, the electric organs are paralysed by dividing their nerves. Like the muscles, the electric organs, after being thus paralysed, may be made to act by pinching the nerve below the line of section. Like the muscles, the electric organs are thrown into a state of involuntary action by strychnia. Like the muscles, the electric organs cannot go on acting without intervals of rest. And lastly, the nerves of the electric organs, like the nerves of the muscles, when somewhat exhausted, respond in the same curiously alternating way to the action of the "inverse" and "direct" current, if only discharge be taken as the equivalent of contraction. In a word, these analogies may be said almost to necessitate the conclusion to which Matteucci was led in regarding them, namely this—that muscular action is accompanied by a discharge of electricity analogous to that of the torpedo. And certainly this conclusion is borne out rather than contradicted by the phenomenon of secondary contraction which is exhibited in a prepared frog's leg, when, after laying its nerve upon the muscle of another such limb, contraction is produced in the latter limb; for here the only sufficient explanation would seem to be that offered by Becquerel, namely this—that contraction happens in the first limb because its nerve is acted upon by an electrical discharge developed in and around the muscles of the second limb during action—a discharge which may not indirectly show that there was a charge to be discharged during the previous state of rest. In a word, the evidence, direct and indirect, must surely suffice to show that the idea of charge during rest and discharge during action is something more than a mere matter of imagination.

Nor can it be fairly urged that the force of the natural electricity of the muscle is too feeble to produce the results attributed to it. On the contrary, after what has been said respecting the analogies between muscular action and the

action of the electrical organs of the torpedo, it is quite fair to suppose that the force of the discharge in muscular action, instead of being feeble, may be equivalent to that of the torpedo; and that the reason why it cannot be detected in the same way may be that it is short-circuited, and so mainly out of reach, within the body.

3. *How in nervous action electricity may do much of what is commonly believed to be the work of a vital principle.*

There is good reason to believe* that the electrical law of nerve-fibre differs in no wise from that of muscular fibre.

There are also similarities between the principal structural elements of the nervous system from which it would appear that what holds good of one part of this system electrically may hold good of the other parts also. Nay more, there is in these facts reason for believing that what holds good of nerve-tissue generally may hold good of muscle also, for the typical element of nerve and muscle is evidently one and the same.

Looking at the different parts of the nervous system—ganglionic cells, and the peripheral nerve-organs—and at muscle cells and fibres, it is easy to trace the same structural plan.

Central ganglionic cells, as seen in the ganglia of the sympathetic system, and in other small ganglia of the kind, consist of a round, oval, or pyriform mass of soft translucent, granular substance, with which two or more nerve-fibres communicate, and of an enclosing capsule formed of a transparent membrane with attached or embedded nuclei. The central granular substance, with which the nerve-fibres communicate, and the investing capsule, are unmistakable in the ganglionic cells of the minute ganglia, but not so in the brain and spinal cord. In the brain and spinal cord there is the same central substance, but the proper cell wall is doubtful. Moreover, the central substance, instead of being a round, oval, or pyriform mass, with which the nerve-fibres are connected at one point only, branches out into several processes, which seem to be continuous with the nerve-fibres. At the same time, these cells and fibres are surrounded and supported by connective tissue, called reticulum by Kolliker, and neuroglia by Virchow—a tissue which, as Dr. Sharpey points out, "is not merely an open mesh-work, but consists of fine laminae formed of a close investment of finest fibrils, disposed as membranous partitions and tubular compartments for supporting and enclosing the nervous bundles;" so that, in the brain and spinal cord, as in the smaller ganglia, there is good reason for believing that the structure of the ganglionic cell is virtually the same, namely, a central granular mass, with which nerve-fibres are connected, and a membrane, with nuclei, investing this mass.

The peripheral nerve organs, of which the principal forms are three in number—the end-bulbs, the touch-corpuscles, and the Pacinian bodies—agree in having (1) an inward part or core of soft, translucent, finely granular matter, in which one or more nerve-fibres end by bulbous, or knobbed extremities; and (2) an outer investing capsule of ordinary connective tissue, with nuclei. In the end-bulbs and touch-corpuscles this capsule is simple; in the Pacinian body it is made up of many concentric layers, from forty to sixty in number, with nuclei, these layers, "encasing each other, like the coats of an onion, with a small quantity of pellicular fluid included between them," being strung together where the nerve passes through. The structural plan is still that of the ganglionic cell—a central mass of granular matter, with which nerve fibres are intimately connected, and an investing capsule, simple or complex, as the case may be; and this would seem to be the plan of all the peripheral parts of the nervous system without exception, for it is a question

* See NATURE, Jan. 4, 1872.

whether nerves do ever *terminate* in plexuses or meshes of any kind.

The fibre of voluntary muscle is said to consist of a large number of extremely fine filaments enclosed in a transparent, homogeneous, elastic (the composition agrees with that of elastic tissue), tubular sheath, called the sarcolemma or myolemma, in which are nuclei, called muscle-corpuscles. It might, however, be more correct to say that this fibre consists of a mass of soft granular matter (the granules being the *sarcous elements* of Bowman), agreeing in the main with the granular core of the ganglionic cells and peripheral nerve-organs, enclosed in the sheath which has been described; for the contents of the fibre, instead of splitting up longitudinally into filaments, may split up horizontally into discs—may split either way or any way, in fact, as they would do if they were made up, neither of fibrils nor discs, but of granules which may, as it happens, aggregate into fibrils or discs. The fibre of involuntary muscle, on the other hand, is made up of elongated fibre-cells, connected together by a homogeneous, transparent uniting medium, without any sarcolemma. Each of these fibre-cells has a core of finely granular matter, sometimes arranged so as to form imperfect fibrils, and of a distinct cell-membrane, with nuclei, the shape of the cell being fusiform, with ends sometimes pointed, sometimes truncated, sometimes simple, sometimes branched. The cell-membrane in reality takes the place of the sarcolemma, for each cell is nothing more or less than a rudimentary fibre. Indeed, in long voluntary muscles there are fibres which seem to partake somewhat of the character of voluntary and somewhat of the character of involuntary fibres—fibres which, instead of running continuously from one end of the muscle to the other, are made up of several elongated fusiform cells, overlapping each other at the ends, and which therefore may consist of cell-membrane and sarcolemma both. Nor is the connection of the nerves with the muscular fibres or cells peculiar. Beale and Kölliker think that the nerves belonging to voluntary muscle end in meshes of pale fibres outside the sarcolemma. Rouget, Kühne, and others are of opinion that this ending is in peculiar organs—motorial end-plates continuous with the axis-cylinder of the nerve, oval or irregular in shape, within the sarcolemma and between it and the proper muscular substance, the primitive nerve-sheath fusing with the sarcolemma, and one end-plate being devoted to each muscular fibre. And thus it may be that the muscular fibre or cell may agree in structure with the ganglionic cell, and the peripheral nerve organ, in having a soft granular core, with which one or more nerve-fibres are connected, and an investing membrane of connective tissue with one or more nuclei. It may be, indeed, that the muscular fibre and cell are only varieties of the peripheral nerve-organ.

The nerve-fibres by which these several bodies—ganglionic cells, peripheral nerve organs of various kinds, and muscular fibres and cells—are connected together, are of two kinds, the tubular, which are white with dark borders, and those which are grey, pale, non-medullated or gelatinous. The white or tubular fibres, when quite fresh, appear perfectly homogeneous like threads of glass, but afterwards, when coagulation has taken place, they are found to consist of an axis, or primitive band, as it is called, a white medullary coating strongly refractive of light, and giving them the appearance of having dark borders, and an outer membranous sheath or tube, with nuclei in it, agreeing in composition with elastic tissue, and being analogous to the sarcolemma. The grey, pale, gelatinous fibres would seem to consist of the axis or primitive band of the others, with obscure sheaths in which are nuclei, but without medullary coating. They belong chiefly to the ganglionic system, but not exclusively; at all events the finer subdivisions of the white dark-bordered nerves of the other systems are found to have lost their dark borders, and to have become undistinguishable

from those which have no dark borders naturally. In nerve-fibres, therefore, as in nerve-cells, there would seem to be a central core, and a membranous investment containing nuclei; and, all things considered, the connection of these fibres with ganglionic cells, with peripheral nerve-organs, and with muscular fibres and cells, would appear to be by one and the same method, the axis or primitive band being continuous with the central soft granular core of the central and peripheral elements of the nervous system, and of the muscular fibres and cells (for with so many points of analogy it is difficult not to believe with Rouget, Kühne, and others who agree with them in this matter), the primitive sheath, when there is one, being continuous with the membranous investment of this core, neurilemma, sarcolemma, or other, as the case may be.

Instead of being peculiar, therefore, the voluntary muscular fibre may be no more than a modified form not only of the contractile cell of the involuntary muscular fibre, but also of the nerve-fibre, and of the central and peripheral cell-elements of the nervous system. The same type of structures is to be traced out in each case. There is in each case the same central, granular, soft, substance, but slightly changed protoplasm probably, in the molecular change of which an electrical change may originate. There is in each case outside this central substance a membrane which may become charged leyden-jar-wise as the neurilemma and sarcolemma are supposed to be charged. And, therefore, it is not altogether begging the question to conclude that in each case one and the same electrical law may bear rule.

And certainly the adoption of this idea is calculated to elucidate much that is obscure in the structure and action of the nervous and muscular systems.

Upon this view a use is found for the contents and walls of the fibres and cells of which the nervous and muscular systems are made up. The contents are wanted for the generation of the charge; the walls are wanted for receiving and holding this charge. Their leyden-jar office, indeed, explains why it is that the nervous and muscular systems should be made up of cells and fibres.

Upon this view one use is found for the nucleus in the walls or sheath of cell or fibre. The nucleus may represent the spot at which the development of this wall or sheath is arrested—the spot at which the original, moist, conducting protoplasmic matter is not transformed by drying, or in some other way, into non-conducting wall or sheath, and, therefore, as I think, the nucleus may have a very definite function to fulfil. As I think, indeed, the case may be this: that the molecular changes in which the charge of the cell or fibre originates (those in the contents of the cell or fibre) depend upon the continual ingress of fresh and egress of used-up aerated matter; that this ingress and egress is, not through the wall or sheath anywhere or everywhere, but only through the nucleus; that the one charge not wanted for charging the inner surface of the wall or sheath may escape to earth through the nucleus; and that the channel of the discharge which happens when the cell or fibre passes from the state of rest into that of action may also be through the nucleus. Without such opening as may be supposed to exist in the nucleus, indeed, it is difficult to understand how the cell or fibre should be charged and discharged; and thus, upon the view in question, a use is found (not the only use, of course), for the nuclei present in the walls of the cells and in the sheaths of the fibres of the nervous and muscular systems.

Upon this view, too, the infinite number of these cells and fibres may in some degree be accounted for. For may it not be that each cell and fibre acts as a condenser to every other cell or fibre, so that a charge or discharge which is feeble without being multiplied becomes anything but feeble when multiplied? And may not this function of a condenser be the one function of the Pacinian bodies?

Other cells and fibres have other functions as well; these bodies may have this one function only. They may, in fact, be rudiments of the electric organs of the torpedo, with a sphere of action, not without the body, but within it. And this may be the reason why these bodies are placed on the trunks of nerves at points where it may be supposed that special means are wanted for keeping up the requisite degree of elastic tension, their use in this case being analogous to that of an ordinary leyden condenser in connection with a telegraph wire conveying a minimum amount of electricity.

Nor does this view fail to elucidate in some degree the way in which nerves tell upon muscle and react upon each other. Let the contents of the muscular fibre or cell be connected with the contents of the corresponding ganglionic cell by the axis cylinder of the nerve, and a charge or discharge in the nerve centre must tell upon the muscular tissue, just as in the case of two leyden jars with their inner coatings connected by a conductor, the charge or discharge of the one involves corresponding changes in the other. Let the case be that of a sensory peripheral cell and a central ganglionic cell, similarly connected, and a charge or discharge in the former will involve a charge or discharge in the latter, the discharge producing sensation. The case is simply that of a leyden battery, with all possible space economised by making the conductors, where they may, do the work of the jars. The case is plain as regards the charge, for the molecular charges are ever at work by which it is kept up and renewed; and the case is not altogether obscure even as regards the discharge, for it may well be that discharge happens when the charge increases until it overleaps the barrier of insulation presented in the dielectric walls of the fibres and cells—a result which, for want possibly of a sufficiently insulating barrier somewhere, happens more easily than it ought to do in the case of involuntary nervous action, such as is seen in convulsion, neuralgia, and the rest.

Viewed in this way, too, it is easy to see that the nervous system may do its work, not by discharge only, but by charge also. It is easy to see that the discharge may be all that is wanted to cause contraction; indeed, according to the premises, all that is wanted for this purpose is that the charge which kept the muscular fibre elongated should be discharged, and the fibre so left to the play of its own natural elasticity. It is easy to see, also, that discharge may be the mechanical agent which may call the various nerve-centres into action—by shaking the veil which separates the visible from the invisible in the higher mental processes, perhaps. And for charge no less than discharge it is also easy to see that there may be a definite work to do—a work of which the end is, not to cause action in the muscles and in the various nerve-centres, but to prevent it. Indeed, after what has been said, it is to be supposed that all nerves, through their electricity, have during rest an action which Pflüger supposes to be peculiar to certain nerves only, and to which he gives the name of *inhibitory*.

And here opens out a question of paramount interest.

It has been seen that the electric law of nerve and muscle is one and the same. It has been seen that the state of contraction in muscle is antagonised by the presence of a charge of electricity in muscle—that a state of actual elongation is produced by the action of this charge. It has been seen, not only that the state of contraction is antagonised and a state of elongation set up by the presence of the natural charge of electricity in muscle, but that more marked changes of the same kind are produced by the action of an artificial charge of electricity, provided this charge be greater in amount than the natural charge. The facts, indeed, are calculated to justify the notion that the degree of elongation produced by the conjoint action of the charge belonging to the muscle itself and the charge

imparted to the muscle from its nervous system is greater than that produced by the action of the former charge singly; or, in other words, that the charge imparted to the muscle by its nervous system may cause a degree of elongation in the muscle which is over and above that caused by the charge belonging to the muscle itself—which surplus may have much to do in explaining rhythmic action in hollow muscles.

Take the case of a hollow muscle—a capillary vessel, for example. This vessel has its special nervous system, vasomotor nerves, efferent and afferent, vasomotor centre; and the question is as to how this system acts upon the vessel. May it be that a charge of electricity is continually being developed upon the cell-walls and fibre-sheaths of this system by the action of the oxygen of the blood and other causes upon the contents of the cells or fibres; and that this development goes on until, the bounds of insulation being overpassed, discharge happens? May it be that the muscular fibres forming the walls of the vessel elongate, and in so doing cause the vessel to dilate as long as this charge is imparted to them? May it be that the vessel passes from the state of dilatation into that of contraction when the discharge of this charge happens, in consequence of the muscular fibres being then liberated from the condition of extra-elongation caused by the charge imparted to them from the nerves, and so left to the play of their natural elasticity? May it be that thus there are diastolic and systolic changes in the vessel by which the blood is alternately drawn into and driven out of the vessel, changes which may supply the key to the mystery of “capillary force”? Nay, more; may it not be that the diastolic and systolic movements of the heart itself may have to be explained in the same way? To all these questions I answer, unhesitatingly, yes, it may be so. Indeed, after what has been said, the only explanation which seems to be called for concerns the movements of the auricles of the heart, and this is easily given: for, as it seems to me, the auricles must be looked upon chiefly as cisterns formed of dilated veins, and their movements chiefly as passive consequences of the movements of the ventricles, the systole of the auricles being little more than the passive falling-in of the auricular walls upon the blood being suddenly sucked away by the ventricular diastole, the diastole of the auricles being little more than the passive bulging-out of the auricular walls, caused at one and the same time by the stream of blood which is ever flowing in from the valveless openings of the great veins, and by a forcing back of this stream, consequent upon the sudden closure and recoil of the auriculo-ventricular valves at the moment of the ventricular systole. In this way the seemingly diastolic and systolic movements of the auricles must alternate with the true diastole and systole of the ventricles, and, at the same time, the absence of valves at the opening of the great veins into the auricles is accounted for—an absence altogether inexplicable if the auricular systole had to play the *active* part in the circulation which is played by the ventricular systole. And much to the same effect may be said of rhythmic movements in other hollow muscles, the chief difference between one such movement and another being perhaps this—that contraction follows upon dilatation more slowly in consequence of the cell-walls and fibre-sheaths of the special nervous systems being constructed differently as regards the capacity for quick charging and discharging; but these hints must suffice for what might be said upon this subject.

Nor can it be urged as an objection to this view of nervous action—the only objection which may be urged, so far as I know—that the state of action in nerve-fibre is unattended by the contraction which attends upon action in muscular fibre. The electrical law of nerve and muscle being one and the same, it might be expected, perhaps, that this particular difference should not exist; but this difficulty, if it be one, is soon disposed of. Thus,

the success of the experiment with the elastic band depends upon the band being of a certain thickness, and upon the weights being so adjusted as to balance without overbalancing its elasticity. Failing these conditions charge and discharge may not tell in causing elongation and contraction. And, therefore, the absence of perceptible elongation and contraction in the nerve-fibre under the charge and discharge may be simply owing to the fact that the thickness and stretching of the neurilemma have not been adjusted for the production of these results. Besides, it is by no means certain that there are not in some nerve-fibres slight changes which are strictly parallel to the elongation and contraction witnessed in muscular fibres.

In a word, there seems to be good reason for believing that in nerve as in muscle electricity may have to do much of what is commonly regarded as the special work of an inherent vital principle.

4. How in maintaining the "tone of the system" electricity may have to do much of what is commonly regarded as the special work of a vital principle.

After what has been said little remains to be added under this head. The conclusion arrived at is that each perfect fibre and cell of living muscle and nerve (and, by implication, every living fibre and cell), is a charged leyden-jar while at rest. It is that the membranous portion of the fibre or cell is at this time compressed by the mutual attraction of the two opposite charges disposed leyden-jar-wise upon its two surfaces. It is that the effect of this compression is to elongate the fibre or cell by squeezing out this membrane lengthwise. What then? May it be that this compression, this squeezing out, is sufficient to account for what is called the "tone of the system"? This state, no doubt, is indefinite enough, but it becomes more definite when viewed in this way—so definite, in fact, that here also, in the maintenance of the "tone of the system" that is to say, electricity may have to do much of what is commonly believed to be the work of a vital principle.

5. How in certain processes of growth electricity may do much of what is commonly regarded as the special work of a vital principle.

A cell or fibre is at first a mass of protoplasm without any investing membrane. Later, this membrane makes its appearance, and how is this? Is it that the surface of the protoplasmic mass, except at the part or parts where the nucleus is afterwards met with, hardens by desiccating, or dying, or changing in some other way, and, so hardening, acquires dielectric properties? Is it that the molecular changes ever going on in the protoplasmic matter beneath this crust, develop a charge on the inside of this crust, which, acting inductively, leads to the development of the opposite charge on the outside? Is it that the compression arising from the mutual attraction of these opposite charges, causes the crust to stretch out every way, and so separate from the underlying protoplasmic mass, leaving thereby in some instances a vacuole, which may be filled with a thin liquid or even air? Is this the way in which the sarcolemma and neurilemma, the cell-walls, and all membranes more or less analogous to them, may be formed? After what has been said such an idea is by no means improbable. Nay, such an idea may be looked upon as the natural consequence of the premises. And if so, then electricity may have to do much of what is commonly believed to be the work of a vital principle in these phenomena of growth, as well as in the various processes which have been already passed in review, and upon which so much has been said as to leave only room now for these bare hints of what might be said upon the subject.

C. B. RADCLIFFE

MERCURY PHOTOGRAPHS

AN entirely novel method of photographic printing has just been discovered by M. Merget of Lyons. Although akin in some respects to the daguerreotype process, it differs essentially therefrom in the fact that exposure to light is not necessary to the formation of every separate image. It is difficult indeed just now to apply any distinguishing name to M. Merget's invention, for the methods hitherto discovered—and the number of these has, we all know, increased of late beyond all calculation—are all of them divisible into two very distinct classes. Thus we have those processes broadly termed chemical, in which every print is secured by the aid of light, as for instance, the nitrate of silver and carbon methods; and those again where a matrix, or printing block, having been prepared, the copies are struck off in the ordinary lithographic or printing press; photographs prepared in this latter manner are usually termed photo mechanical prints. M. Merget's invention partakes singularly enough of the nature of both classes; for while the prints are undoubtedly formed by chemical action, the question of light is of no moment at all, and the manipulations involved are to some extent of a mechanical nature.

The experiments of Faraday upon the diffusion of gases will be remembered by many, and it was the results arrived at by that distinguished philosopher that incited M. Merget, the Professor of Physics at the Faculté des Sciences of Lyons, to take up the investigation he has so successfully carried through. Faraday had already found out that the vapour of mercury acted very sensibly upon gold-leaf, and the first task undertaken by M. Merget was to discover whether this same action also took place upon other metals or their compounds. The investigation, it should be stated, was designed to be of a purely theoretical nature, and was not undertaken, in the first instance at any rate, with a view of working out any practical processes such as may eventually result from the research. The principal points discovered by M. Merget may be thus summarised:—

1. The vapourisation of mercury is a continuous phenomenon; that is to say, the metal emits vapour at all times, even at a very low temperature, and when in a solidified form.

2. Mercury vapour may be condensed upon certain substances, such as carbon, platinum, &c., without these latter being chemically affected.

3. Mercury vapour will pass with exceeding facility through porous bodies, such as wood, porcelain, &c.

4. The salts of all precious metals when in solution are very sensitive to the action of mercury vapour, which has the effect of rapidly reducing them.

The most sensitive to mercury of the precious metal salts are nitrate of silver and the soluble chlorides of gold, palladium, and iridium, and paper prepared with any of these forms at once a most delicate test for the volatile metal; but the solutions must contain some hygroscopic body to prevent complete desiccation, so that the surface coated with them will always remain in a moist condition. To demonstrate how exceedingly sensitive this test-paper is to mercury, we may state that its contact with any body containing but a slight trace of amalgam suffices to darken the surface, while it is affirmed that any workman who has been employed for some time in a looking-glass or other similar factory, may produce an impression of his hand by simply laying the same upon a sensitive surface of this kind, the minute traces of mercury in the pores of the skin being amply sufficient to bring about a reduction of the salt, and to produce consequently an imprint of the fingers. In the same way a section of wood exposed to mercury vapours, and afterwards pressed in contact with a sheet of sensitive paper, prints off upon the surface all the rings and markings it possesses, the mercury being deposited in the pores of the wood in a more or less condensed form.

In the event of nitrate of silver being used for preparing the paper, it is necessary, obviously, to exclude the light, as otherwise a reducing action will be already set up by solar means alone, but with the salts of palladium or platinum no such action need be feared. According to the kind of metallic salt employed, so the tint of the impression varies, but in most cases an intense black may be obtained where the action has proceeded far enough.

Having described M. Merget's discoveries thus far, it is easy to guess how that gentleman employs them in the carrying out of a photographic process. An ordinary glass negative, possessing an image which has been formed by the deposition of silver particles, is prepared in a suitable manner to protect it from injury by contact with the mercury (such, for instance, as coating it in some way with platinum or carbon particles), and the picture is then exposed to the action of mercury vapour. The vapour condenses, in a more or less concentrated form, upon the image—in the same way, pretty well, as it becomes deposited upon, and develops, the latent image in the daguerreotype process—and subsequently the plate thus treated is brought into contact with the sensitive paper. The consequence is that the minute particles of mercury deposited all over the image exercise a reducing action upon the salts on the surface of the paper, and a print results of the original photograph, possessing the same gradation of tint as the original. Indeed, when nitrate of silver is employed for sensitising the paper, the photograph secured is in every respect similar to that produced by light in the ordinary silver printing process, and the picture is forthwith toned and fixed in the same way, in fact, as one of these; in the one case, however, the reduction of the silver salts has been brought about by mercury vapour, while in the other light alone has been the reducing agent. Impressions obtained by means of platinum and palladium salts need simply to be washed in water in order that they may be permanently fixed. These latter, in truth, are so indestructible and inalterable that they cannot be destroyed except by a chemical agent which would at the same time radically injure the paper, or other basis, upon which they rest.

This process of photography is not yet in such an advanced state as to be of any practical importance; but, nevertheless, it is certainly one of the most ingenious and interesting discoveries made of late in this branch of Science. The great advantage it possesses is that of printing without the aid of light, and yet producing prints with detail and half-tone dependent upon delicate chemical reaction—such rare gradation being secured as our present light-printed pictures (silver and carbon prints) alone possess. A mechanical printing process could, of course, easily be worked out from these data, if considered desirable; and, indeed, it is by no means improbable that this will be the most successful way of applying the discoveries in a practical form. But even in the event of no practical use at all being made of the process—for this is indeed questionable—the research, regarded from a purely scientific point of view, is deserving of the highest eulogium.

H. BADEN PRITCHARD

NOTES

In another column will be found full details of the observations of the Total Eclipse of December 12, made at Bekul, by Mr. Norman Lockyer and Captain Maclaur. In future numbers we hope to give similar reports from the observers at the other stations. The weather was very favourable at all the stations, with only one exception.

M. JANSSEN writes as follows to the French Academy of Sciences, under date Shooloor, Neelgherry, 12th of December, 1871, 10 A.M.:—"I have just observed the eclipse, only a few moments since, with an admirable sky, and whilst still under the

emotion caused by the splendid phenomenon of which I have just been a witness, I address a few lines to you by the Bombay courier, who is to start instantly. The result of my observations at Shooloor indicates without any doubt the solar origin of the corona, and the existence of matter beyond the chromosphere."

And in a letter to M. Faye, written half an hour later, he says:—

"I have just seen the corona, as it was impossible for me to do in 1868, when I was entirely occupied with the spectrum of the protuberances. Nothing can be finer, nothing more luminous, with peculiar forms which exclude all possibility of a terrestrial atmospheric origin. The spectrum contains a very remarkable brilliant green line already indicated; it is not continuous, as has been asserted, and I have found in it indications of the obscure lines of the solar spectrum (especially D). I believe the question whether the corona is due to the terrestrial atmosphere is settled, and we have before us the prospect of the study of the extra-solar regions, which will be very interesting and fertile."

PROF. HUXLEY's friends, and the scientific world generally, will learn with great regret that he has been compelled to relinquish all work for the present, his medical advisers having ordered him complete rest for two months, for which purpose he has just started for Egypt. There is every prospect that at the end of the time he will return to his old work with renewed vigour.

THE Regius Professorship of Physic in the University of Cambridge has become vacant by the resignation of Dr. Bond, who has held the office since 1851.

THE Council of the College of Preceptors has arranged for the delivery of a series of three lectures to the members of the college and their friends, on the teaching of science in secondary schools. The first lecture of the series, "On Teaching Physics," was delivered at the rooms of the College, 42, Queen Square, on Saturday evening, the 13th instant, by Professor G. C. Foster, F.R.S.; the second, "On Teaching Mechanics," was delivered yesterday (Wednesday) evening by Prof. W. G. Adams; and the third, "On Teaching Botany and Geology," is to be delivered on Monday evening, 22nd inst., by Mr. J. M. Wilson, of Rugby. The point mainly insisted on by Prof. Foster in his lecture, was the necessity, in order to make the study of Physics of much use as a training for the mind, that the pupils should not only see, but actually make experiments for themselves, so that the principal facts and phenomena discussed may be known to them as matters within their own experience.

A SERIES of lectures will be delivered in Gresham College, Basinghall Street, by Mr. E. Symes Thompson, M.D., F.R.C.P., as follows:—Thursday, January 18, 1872, On the Digestive Organs in Health and Disease (continued from last course); Friday, January 19, 1872, On the Blood Vessels; Saturday, January 20, 1872, On the Pulse.

AT the first Anniversary Meeting of the Anthropological Institute, held January 15, Sir John Lubbock, Bart., M.P., F.R.S., president, in the chair, the president delivered an address, and the officers and councils to serve for 1872 were elected as follows:—President—Sir John Lubbock, Bart., M.P., F.R.S.; Vice-Presidents—Mr. W. Blackmore, Prof. Busk, F.R.S., Dr. Charnock, Mr. John Evans, F.R.S., Mr. George Harris, Prof. Huxley, F.R.S.; Director—Mr. E. W. Brabrook; Treasurer—Mr. J. W. Flower; Council—Mr. H. C. Bohn, Captain R. F. Burton, Mr. James Butler, Mr. A. Campbell, M.D., F.R.S., Mr. Hyde Clarke, Mr. J. Barnard Davis, M.D., Mr. Robert Dunn, Mr. David Forbes, F.R.S., Colonel A. Lane Fox, Mr. A. W. Franks, Sir Duncan Gibb, Bart., M.D., Mr. Joseph Kaines, Mr. Richard King, M.D., Mr. A. L. Lewis, Mr. Clements R. Markham, Captain Bedford Pim, R.N., Mr. F. G. Price, Mr. C. Robert de Rulhières, Mr. Spottiswoode, V.P.R.S., Mr. C. Staniland Wake.

MR. SAMUEL SHARPE has presented the sum of 4,000*l.* to University College towards the building fund, and Mr. J. Pemberton Heywood has given a donation of 1,000*l.* towards the same object. The executors of the late Mr. Felix Slade have given 1,600*l.* towards the cost of the fine-art buildings and to provide casts and other appliances for the students.

AT a recent session of the Council of University College, it was decided to admit ladies attending the class of political economy to compete for the prizes and also for the Hume and Ricardo Scholarships awarded for proficiency in that science.

THE young Hippopotamus, which we announced as having been born on Tuesday last week at the Garden of the Zoological Society, died the following day. The body has been sent for dissection to Prof. Humphry at Cambridge. We may hope therefore to hear more of him in the pages of the *Journal of Anatomy and Physiology*, which is edited by the professor.

WE are informed that the next number of the *Quarterly Journal of Science* will contain a detailed account by the editor of the scientific principles involved in the A B C Sewage Company's process, of which, according to the *Times*, Mr. Crookes, F.R.S., has accepted the scientific direction.

THE first part is just published at Leipzig of a new edition of Pritzell's "Thesaurus Litteraturæ Botanicae," or index of works on the various branches of botany, published in all languages, from the earliest times. As it is more than twenty years since the publication of the last edition, the additions are very numerous.

THE President of the Medical Society of the county of New York, Dr. Abraham Jacobi, has placed in the hands of its treasurer 400 *dols.*, to be awarded for the best essay on "A History of the Diseases of Infancy and Childhood in the United States, and of their Pathology and Therapeutics." Competitors will send their essays in English, with motto attached, and address of the writer, with the same motto, in a sealed envelope, to the present Secretary of the Society, Dr. Alfred E. M. Purdy, 123, East Thirty-eighth Street, on or before January 1, 1873. The committee are authorised by the society to withhold the prize if the essays submitted should not merit it.

DR. J. W. FOSTER, President, and Mr. William Stimpson, Secretary of the Chicago Academy of Sciences, have issued a circular informing the scientific world of the extent of the losses suffered by the Institution through the calamitous fire in that city. These comprise, besides a very large number of other collections of great value, the Audubon Club collection, consisting of very finely mounted specimens of the game birds and mammals, both of America and of Europe and Asia, about 400 in number; the State collection of Insects, recently purchased by the State of the heirs of the late State Entomologist, Mr. B. D. Walsh, for 2,000 *dols.*, but of great scientific value from the number of types it contained; the splendid series of specimens illustrative of the natural history of Alaska, collected in 1865-69 by Bischoff and the naturalists of the W. U. Telegraph Expedition; the Smithsonian collection of Crustacea, undoubtedly the largest alcoholic collection in the world, which filled over 100,000 jars, and contained the types of the species described by Prof. Dana and other American authors, besides hundreds of new species, many of which were described in manuscripts lost by the same fire; the Invertebrates of the U.S. North Pacific Exploring Expedition, collected in great part in Japanese seas by the secretary in 1853-56, which besides Crustacea, included in the last item, embraced great numbers of Annelids, Mollusca, and Radiata, most of which remain as yet undescribed, except in manuscripts lost; the collection of the marine shells of the coast of the United States, made by the secretary and his correspondents during twenty years of dredgings and general research on every part of the coast from Maine to Texas; nearly every species was

illustrated by specimens from every locality in which it occurs, not only on our own shores, but on those of Europe and the Arctic Sea, and in the Tertiary and Quaternary formations, showing the effect of climatic influences, geological age, &c.; this collection embraced about 8,000 separate lots of specimens; the deep-sea Crustacea and Mollusca, dredged in the Gulf Stream by M. Pourtales, of the U. S. Coast Survey, in the years 1867, '68, and '69, which had been placed in the hands of the secretary for description; the results of the deep-sea dredgings in Lake Michigan, by the Academy in 1870 and 1871, the work of the latter year having been performed by Mr. J. W. Milner; the Arctic collections of the late Director of the Academy, Robert Kennicott, made during the years 1859-61. The general collection contained about 2,000 mammals, 30 mounted skeletons, including two mastodons, an African elephant, sea otter, elephant-seal, &c., 10,000 birds, 1,000 nests of eggs, and a great quantity of eggs without nests, 1,000 reptiles, 5,000 fishes, including many large sharks and rays, 15,000 species of insects and other arthropods, 5,000 species of shells, with immense numbers of duplicates, 1,000 jars of molluscs in alcohol, 3,000 jars or "lots" of radiates, including several hundred corals, 8,000 species of plants, 15,000 specimens of fossils and 4,000 minerals. In Archaeology there were about 1,000 specimens, all American; and the Ethnological collection embraced a very fine series of the clothing and implements of the Esquimaux of Anderson River, collected by Robert Kennicott and his Arctic friends, and presented by the Smithsonian Institution. The Academy desires to announce that although now laid prostrate by the terrible disaster it has suffered, it will soon rise to refill its place among its sister institutions. The trustees have determined to build up again the material interests of the Institution, notwithstanding the terrible losses which they, in common with all of its patrons, have suffered. The publication of its Transactions will soon be resumed. The Academy would therefore take this opportunity to appeal to its correspondents for the donation of their own publications of the past few years, to replace those lost, for which it was also indebted to their generosity.

PROF. NATHAN SHEPPARD, of the University of Chicago, has written to the papers to state the present position of the University of Chicago, and of the Observatory, which is well known in the astronomical circles of Europe. The buildings fortunately escaped, but the fire has left the University in very serious financial difficulties. Many of the gentlemen upon whom the University, and especially the Observatory, was dependent are so reduced in circumstances as to be unable to meet their engagements. The consequence is that the resources of the University are suddenly and greatly abridged. In fact, its income, aside from its tuition fees, is entirely cut off. The Observatory is the first department to feel this loss. A letter just received from Chicago says it is feared that the eminent director, Prof. Truman H. Safford, would be obliged to leave his post for want of support. This will be sad news to the professional correspondents of Prof. Safford in Europe. When the University was founded, about fifteen years ago, a few public-spirited gentlemen rallied around it, and under their self-sacrificing care it has been housed in a commodious and elegant (although unfinished) building, at a cost, including Observatory, telescope, &c., of about forty thousand pounds; and now has, in all departments of study (preparatory, classical, scientific, and law), twelve professors and about 250 students. In conclusion, the Professor, dating from 77, Upper Thames Street, London, asks any reader who would care to lend a helping hand to do so, and to follow in the wake of a Scotch gentleman who has generously offered to head the subscription list with 50*l.*

INOCULATION has by the Indian Legislature been forbidden in the districts of the twenty-four Pergunnahs, Nuddwa, Burdwa, Hooghly, and Howrah in Bengal.

THE FOUNDATION OF A TECHNOLOGICAL EDUCATION*

TECHNOLOGICAL education is taken up by many writers on the subject at the time when a youth is supposed to enter the School of Technology; and scientific men, as a rule, do not seem to set sufficient stress upon the necessity of laying the foundation for it at a much earlier age. It is not indeed scientific men alone who are interested in this question, but they are the authorities who should speak out upon it, for they alone are competent to pronounce an opinion upon the value of scientific education. It cannot be expected that men who themselves know nothing of science, care nothing for its progress, and recognise none of the obligations under which they lie to it, should favour its introduction into our schools, and thus depart from the stereotyped and antiquated system of education, that brings up our youth but partially fitted or altogether unprepared for a majority of the occupations they are destined to pursue, and exposed at every point to suffer from their own ignorance and the impositions of others. Every one now-a-days should have such a knowledge of scientific principles and methods as will enable him to form a just idea of the value of science, and to distinguish between knowledge and pretence—between science and quackery. The political economist, who has to legislate regarding the natural resources of the country; the capitalist, who invests in their development and manufacture; the lawyer, who has to conduct the numberless suits into which scientific questions enter; the journalist, who claims to enlighten and direct the masses; every one who uses manufactured products liable to adulteration; every one who values his health, or has to consult a medical man or other scientific expert; every father, and, what is still more important, every mother of a family; every youth that is making choice of an occupation for life; or, in other words, every member of a civilised community, ought to be acquainted with the elementary facts and principles upon which all the applications of science are based.

This knowledge, which should thus form an essential feature of general education, is also that which will form the very best foundation for technological purposes. In the first place, it will bring into technological schools a vast amount of excellent material that is now wasted elsewhere; for numbers of youths, with minds well adapted to such pursuits, would take to the practical applications of science, if they knew anything at all of science itself. Nor need there be any fear that the field will thereby be overcrowded; for so long as quacks and pretenders abound there is room for good men, and the difficulty at present is to obtain students who have a natural aptitude, or, rather, we should say, an aptitude developed by early education for scientific work.

Secondly, and this is the really important aspect of the case, educators will have to deal with material prepared for their purposes, instead of, as now, receiving it not merely unprepared, but actually warped out of proper condition. For it is not too much to say that a youth who has had a purely academic education, on entering a technological institute has to devote a large portion of his time to mastering elementary ideas and principles, that he should have learned as a child; whilst the erroneous methods of instilling knowledge to which he has been subjected, will be a hindrance to him for years, if not for life. It is but a few days since that a freshman in such an institute gravely asked the writer "if a fish was not an animal," thus displaying, at the age of seventeen, a doubt of the meaning of a term that he should have accurately understood at the age of seven. Of a term, did we write? We mean of a fact; of one of the broadest generalisations of science. Now, what has not such a youth to learn of first principles? How utterly unprepared in the simplest rudiments of knowledge is he for a technological course! But when we come to the system of thought induced by the vicious methods of preparatory study, the case is still worse. Here we have the labour of driving practical instruction into the brain of a young man who, after having passed perhaps brilliantly through college, is now laboriously pushing his way through a technological course; he is now nominally near its close, yet three years of steady application have not divested him of the habit of learning by rote on the authority of others. He has no reliance on his own experiences, seeks no explanations by questioning his own reasoning powers, but prefers always to take another's opinion, instead of elaborating a judgment of his own. He is still in fact

utterly devoid of the first essentials of self-help in education, so completely have his natural abilities been misdirected in that first course, in which the amount of evil accomplished may be judged by the very brilliancy of his success in it. Such a student will never make a reliable scientific expert. We should not like to trust him even as a druggist's clerk; he should never have entered a technological institute, because he has never had any foundation laid for a technological education.

But in what is such a foundation to consist? and when is it to be commenced? What alterations are to be made in our recognised systems of instruction? Already there are more subjects to be taught than the child has time to learn. We reply, let this education commence in the very infant school; let the methods of instruction be rational, because natural ones; let the subjects be taught in their natural order; and we may very easily teach, or rather "educate," vastly more than we do now. At present beyond mere reading, writing, some mathematics, and something of languages, this child learns absolutely little, and that little superficially. It wastes its time largely in learning the theoretical use of these tools without being made to apply them in building up an education. This is not the way in which the carpenter instructs his new apprentice; if he did, neither would ever reap much benefit from his instruction.

Let the elements of the natural and physical sciences form a part of general education; let physical geography go before political; let the child learn that a history of the world precedes that of man; and at every point let him be familiarised with the intimate dependence between the truths of science and the fact of his own existence. Let these things be taught by a rational method of object teaching, not used to convey desultory information, but as a system of training, whereby the reasoning faculties may be rightly educated, at the same time that the memory is taxed with a stock of useful, because elementary and connected ideas. Let reading and writing sink to their proper rank, as means of education and not as objects of it; and let them, whilst being taught, be used to aid in the acquirement of real knowledge.

This may seem to demand a radical change in our system of preparatory education public and private; but if the technologist wishes to make the most of young minds, he must bend them to his purpose from their earliest years; nor will the community at large, when it understands that its interests in the matter are identical with its own, be averse to the change proposed, which is in accordance with its needs and the progressive spirit of the age. If the advocates of a liberal and enlightened system of popular education in England can succeed in tiding over the shortsighted opposition of sectarianism, as above sketched out, inaugurated there by the aid of its scientific men; the result will be, that the technological schools of Great Britain will be supplied with materials trained from their very infancy in science. Are there no scientific men in the country who will take up the subject here in the same wide-awake spirit?

MECHANISM OF FLEXION AND EXTENSION IN BIRDS' WINGS*

DR. COUES' proposition is, that flexion of the forearm upon the humerus produces flexion (adduction) of the hand upon the forearm, by osseous mechanism alone, and conversely: extension of the forearm causes extension (abduction) of the hand. The point of the article consists in a demonstration of the fact that, in spreading and folding the wing, the radius slides lengthwise along the ulna to a certain extent. Recapitulating certain points in the anatomy of the elbow and wrist, the author shows that this sliding is produced by the relative size, shape, and position of the humeral surfaces with which the radius and ulna respectively articulate; these being such, that in flexion of the forearm the radial surface is nearest the wrist-joint, and in extension the ulnar one; and consequently the two bones of the forearm occupy different relative positions in flexion and extension. In flexion, the radius is pushed forward, and projects somewhat beyond the end of the ulna, impinging upon the radio-carpal bone (scapholunar), and pushing the pinion around the centre of motion of the wrist-joint so that it is more or less flexed. In extension, the reverse motion takes place, from the pulling back of the radius. The proposition is carefully demonstrated, illus-

* Abstract of a Paper read at the Indianapolis Meeting of the British Association for the Advancement of Science, August 1871. By Dr. Elliott Coues. From the *American Naturalist*.

* By Mr. E. C. H. Day, reprinted from the *New York Technologist*.

strated with three figures, and likewise shown to be susceptible of ocular proof by direct experiment. Several interesting corollaries are also drawn. Some such mechanism is shown to be an anatomical necessity, from the structure of the wrist-joint, to provide for the extremes of adduction and abduction that take place in the wrist, without straining the joint. Another obvious purpose subserved is equalisation of muscular power, by relegating a part of the work, that the hand muscles would otherwise have to perform, to the larger flexors and extensors of the upper arm; and an actual saving of a certain amount of muscular effort, this being replaced by automatic movements of the bones themselves. Having seen no account of this mechanism, the author is inclined to think it may be unnoticed.* It is at any rate a new explanation of the design of the peculiar shape and position of the radial articulating surface of a bird's humerus, far more important than that hitherto assigned—viz., its causing simply the well-known obliquity of flexion of the forearm.

SCIENTIFIC SERIALS

THE number of the *Geological Magazine* for Dec. 1871 (No. 90) contains an unusual abundance of important interesting papers. The first is an article by Prof. Traquair on the genus of fossil fishes to which Prof. Huxley has given the name of *Phaneropleuron*, with the description of new species (*P. elegans*) from the Lower Carboniferous limestone of Burdiehouse. The author describes some new points in the structure of the type-species of this genus (*P. Andersoni*) from the Devonian yellow sandstone of Dura Den, the most important being that the dorsal fin was in that fish continued as a "dorso-caudal" to extremity of the body as in *Lepidostreus* and *Ceratodus Forsteri*. Prof. Traquair gives a restored outline of *P. Andersoni* in accordance with his views, and also figures of two specimens of his new species.—Mr. T. G. Bonney contributes an interesting paper on a double "cirque" in the syenite hills of Skye, with remarks upon the formation of cirques, in continuation of his paper read before the Geological Society some time since.—From Mr. Carruthers we have descriptions of two previously unknown coniferous fruits from the Gault of Folkestone; one of them a magnificent cone, described and figured under the name of *Pinites hexagonus*; the other a smaller form called *Sequoites ovalis*. To this paper the author has appended a note on the structure of the scales of his *Arancarites sphaerocarpus*, with some judicious remarks on the caution which ought to be exercised by the student of fossil plants in determining the affinities of the often fragmentary remains with which he has to deal.—Mr. James Geikie publishes a first paper connected with that apparently inexhaustible subject, the climate of the glacial epoch. In this the author discusses the evidence furnished by the glacial deposits of Scotland with regard to the occurrence of warm interglacial periods, during which all or nearly all the snow and ice may have disappeared from the face of the country.—Mr. A. H. Green's notes on the geology of part of the county of Donegal contain an interesting account of the structure of the county, especially with regard to the relations of the granites and stratified rocks and to the glaciation of the surface.—And lastly, Mr. A. J. Browne, from an examination of the valley of the Yar in the Isle of Wight, throws out the suggestion that that valley and the other river-valleys of the island were originally occupied by continuations of the Hampshire rivers before the excavation of the Solent.—Among the miscellaneous notices we may call attention to an article by Prof. T. Rupert Jones and Mr. W. K. Parker on the Foraminifera from the chalk of Meudon, figured by Ehrenberg in his "Mikrogeologie."

Quarterly Journal of Microscopical Science, January.—"Notes of a Course of Practical Histology for Medical Students," given at King's College, London, by Dr. Wm. Rutherford, F.R.S.E., &c. This paper illustrates the author's method of teaching, the students preparing for themselves the series of specimens of the various tissues. After an enumeration of the tissues so prepared follow some general observations on Examination of Tissues, How to Harden Tissues, How to Soften Tissues, How to make Sections of Tissues, How to render Tissues Transparent, How to Stain Tissues, How to Inject, and How to Preserve Tissues, with notes on cells and cements.—"On the Peripheral Distribution

of Non-medullated Nerve-fibres," by Dr. E. Klein. Part II. This is the continuation of the paper commenced in the last number of this journal, and to be concluded in the next. It deals with the Nerves of the Nictitating Membrane and Nerves of the Peritoneum.—"Remarks on Prof. Schulze's Memoir on *Cordylophora lacustris*," by Prof. Allman, F.R.S.; "Size of the Red Corpuscles of the Blood of the Porbeagle, or Beaumaris Shark, *Lamna cornubica*," by George Gulliver, F.R.S. The mean long diameter of the corpuscles measured $\frac{2}{3}$ of an inch, and the short diameter $\frac{1}{3}$, nearly alike in magnitude to those of the small dog-fish and other Selachii.—"A Note on some Circumstances affecting the Value of Glycerine in Microscopy," by Mr. W. M. Ord. This note suggests that from the action of glycerine on murexide and oxalate of lime, mounted for the microscope, it is impossible not to have some misgivings as to the results of its use in the preparation of tissues for the microscope.—"On Remak's Ciliated Vesicles and Corneous Filaments of the Peritoneum of the Frog," by Dr. E. Klein.—"On the Structure of the Stem of the Screw Pine," by Prof. W. T. Thistelton Dyer. Scleriform ducts were detected by the author in the branches of a *Pandanus*, and crystalline forms of two kinds in the tissues.—"On Students' Microscopes," by Mr. J. F. Payne, with a table of English and foreign microscopes, their features, powers, accessory apparatus, and prices.

Journal of the Quakett Microscopical Club, January.—"Notes on Podisma," by Mr. M. C. Cooke. After describing the minute structure and mode of germination in these fungi, the author proceeds to detail the experiments of Prof. Oersted, from which it has been supposed that the identity of *Podisma* with *Restlin* has been established. The paper concludes with a critical examination of all the known species, one of which it referred to a new genus, and a different order, under the name of *Sarcostroma Berkeleyi*.—"On the so-called Boring or Burrowing Sponge (*Cliona*)," by Mr. J. G. Waller. The object of this paper is to call in question the burrowing proclivities of the sponges belonging to the genus *Cliona* of which *Hymeniacidon celata*, Bowerbank, is the type. This number completes the second volume of the journal.

SOCIETIES AND ACADEMIES

LONDON

Geologists' Association, January 5.—The Rev. J. Wiltshire, president, in the chair. "On the overlapping of several Geological formations on the North Wales border," by Mr. D. C. Davies, of Oswestry. The author stated that the Geological formations of the district ranged upwards from the Llandovery to the New Red Sandstone. Attention was directed to the way in which nearly every one of these overlapped the one below, hiding in its course many of the beds, amounting in some cases to 1,000 feet of strata, which at other points were exposed. The overlaps increase as a rule from north to south, except in that of the Bala and Caradoc beds by the Llandovery, which increase in an opposite direction. The author inferred that the conformability of strata at a given point did not necessarily prove the unbroken sequence or complete series of the beds at that point, and also that conformability between either two consecutive beds of the same formation, or between those of two distinct formations, was not to be expected to extend over a large area. Amongst other facts stated in this paper was the important one that coal seams occur in Permian strata in the neighbourhood of Ifon. The President remarked upon the enormous time required for the production of the phenomena described by Mr. Davies. Prof. Morris explained the geological and physical features of the district, and spoke of the high value of the paper.—"Report of the Proceedings of the Geological Section of the British Association at Edinburgh, 1871," by Mr. John Hopkinson, one of the deputation from the Geologists' Association. In this communication the author succinctly stated the more important features of the opening address by the president, Prof. Geikie, and of the many papers read before Section C at the meeting at Edinburgh last year, and gave interesting accounts of the two geological excursions under the direction of Prof. Geikie.—Mr. J. T. B. Ives communicated the interesting fact of an extensive bed of peat occurring under gravel between Finchley and Whetstone.—Fossils from the glacial deposits of Islington cemetery were exhibited by Mr. Caleb Evans.

* It is indeed not mentioned in the works of Cuvier, Meckel, Tiedemann, Wagner, and other distinguished authors; but Dr. Bergmann, of Göttingen (*Archiv. für Anat.*, 1839, 296), speaks of essentially the same thing, although the results of the mechanism are not so fully shown.—*Edin. Am. Nat.*

Photographic Society, January 9.—Mr. J. R. Sawyer, in a paper entitled "Photography in the Printing Press," gave an account of the history of mechanical photographic printing. He ascribed to Mungo Ponton the discovery of the action of light upon the bichromates when mixed with certain organic bodies, and to Becquerel the first suggestion of employing gelatine and bichromate in conjunction for photographic printing; but to Poitevin is due the honour of having invented photo-mechanical printing. Mr. Sawyer proceeded to describe the improvements which have since been made, referring to the processes of Tessié du Motay, Lichtdruck, Heliotype, &c. He concluded with a description of photo-collographic printing as now practised.—Mr. J. W. Stillman exhibited and described some new Photographic apparatus.—Mr. Henry Whitfield and Mr. R. Phipps were elected members.

GLASGOW

Geological Society, Dec. 14, 1871.—Mr. John Young, vice-president, exhibited specimens of coal from a thin seam, intercalated amidst beds of trappan ash at Glenaruck, near Bowling. He referred to the discovery, by the late Mr. Currie of Bowling, of thin beds of coal amongst the traps of the Kilpatrick hills at Auchintorlie Glen, which clearly established the carboniferous age of these igneous rocks. He also alluded to his own subsequent observation of thin beds of indurated shale, containing fish remains of carboniferous genera, associated with and overlying one of the seams of coal in the same Glen. Since then he had found another thin seam of coal cropping out at a high level in beds of trappan ash on the hills above Glenaruck, in the same neighbourhood. In the specimens of the coal exhibited, the woody fibre of the plants in a carbonised condition is clearly distinguishable; and although of a very foul quality, and considerably altered by the heat of the traps amongst which it is imbedded, yet it still gives off a little flame in the burning. From the same ash-bed he had also extracted a portion of the stem of a species of *Sigillaria*, and he believed the greater part of the woody structure observed in this Glenaruck coal was derived from plants allied to *Sigillaria* and *Lepidodendra*.—Mr. D. Bell submitted portions of the large pitchstone vein at Corriegills, Arran, and of the sandstone in which it occurs, showing that both rocks are much altered along the lines of contact.

HALIFAX, NOVA SCOTIA

Institute of Natural Science, November 13, 1871.—"On a Lophiod fish caught off Halifax Harbour," by Mr. J. M. Jones, F.L.S., president. The little Lophiod fish in the Provincial Museum collection was at first sight regarded by the writer as a Gurnard, but on closer examination it was found to be a Lophiod. The description in the paper, with a figure, were submitted to Dr. Theodore Gill, of Washington, who considered that in the description and figure he recognised the young of the *Lophius americanus* or Sea Devil. It was supposed, however, that the description was slightly defective, and that some characteristic features had been unobserved. The writer did not find the desiderated features in the specimen, and was assured that it never possessed them, as the specimen had been brought to the museum while living and unhurt, and was in the finest state of preservation when examined and described. It was very different from any of the young Lophiods described in Günther's Catalogue, and was, therefore, probably a new Lophiod. The writer referred to two fine specimens of *Lophius piscatorius* lately caught in the Halifax Harbour, one of which had a cod fish in its stomach. He could see no reason for the application of the term *americanus* by American naturalists, as the European and American forms are identical.—On Sir W. Logan and Hartley's Geology of the Precarboniferous Rocks underlying the Pictou Coal Field, by Rev. D. Honeyman. Sir W. Logan, in his Report on the Pictou Coal Field (*vide* Report of Progress from 1866 to 1869, page 7), says: "No evidence was observed by me on McLellan's mountain to show to what epoch these old rocks belong, but masses somewhat similar are noticed by Mr. Hartley on the west side of East River in a position where they have been mentioned in his Acadian Geology by Dr. J. W. Dawson, who considers them to be of Devonian age, and on his authority they will be so distinguished." By the Devonian colouring of Logan and Hartley's map, which accompanies the Report and illustrates it, it would appear that Sir W. Logan intends that the language should apply to a part of pre-carboniferous rocks in the district of Sutherland River as well as the northern part of McLellan's mountain. Now the rocks of the part of McLellan's mountain range indicated belong to the northern part of one of the great

anticlinal Silurian series which extends to the south about nine miles is generally metamorphic and non-fossiliferous. The author was, however, fortunate enough to discover the fossiliferous localities in the series, viz., at Fraser's mountain, the southern extremity of McLellan's mountain, and Blanchard, celebrated in Danzer's Eulogy and elsewhere for its iron deposit. In the former he found Middle Silurian fossils in the western side of the anticlinal, and in the other Middle Silurian fossils on the eastern side of the same anticlinal, of one or both of these Sir W. Logan's Devonian Rocks must be the extension and northern terminus. In this series the author found Lower Helderberg or Upper Ludlow fossiliferous strata overlying the Clinton and Redina fossiliferous of Fraser's mountain, and this is the most recent of the pre-carboniferous rocks of McLellan's mountain. The other part of Sir W. Logan's Devonian area, the Sutherland river containing the Middle Silurian bend which changes the direction of the Silurians, or connects the N. and S. anticlinals of McLellan and Irish mountains with the Silurians to the east, viz., French River, Barney's River, Antigonish, Arisaig, and Lochaber. In this band there are two monoclinical Middle Silurian series: the one commencing in McLellan's mountain, its greenstone forming Blackwood's mountain, the northern extremity of McLellan's mountain range; overlying this to the south is a metamorphic Medina band. Overlying the greenstone of the second monoclinical on the south is a partially metamorphosed band of Medina age, containing abundance of fossils. The lower part overlying the greenstone at St. Mary's Road contains abundance—beds of Orthids and Athyrus. At Sutherland's River Bridge I found indifferently preserved Lingulæ in the same strata.

PARIS

Academy of Sciences, January 2.—After the election of officers and the reading of the report for 1871, M. Delaunay communicated a note on the movements of the perigee and node of the moon.—M. E. Vicaire read a note on the temperature of the solar surface, in which he arrives at the conclusion that this temperature is below 3000° C. (= 5432° F.). M. Faye, M. H. Sainte-Claire Deville, M. E. Becquerel, and M. Fizeau, spoke upon this subject, all of them agreeing in opinion with M. Vicaire. Father Secchi, however, in a third note on the solar temperature, maintained his previous estimate of 10,000,000° C.—M. Chasles read a continuation of his theorems relating to the harmonic axes of geometrical curves; General Morin presented a note by General Didion on the expression of the relation of the circumference to the diameter, and on a new function; and M. Chasles communicated a further note by M. Halphen, on the straight lines which fulfil given conditions.—A note on the electrical currents obtained by the flexion of metals, by M. P. Volpicelli, was read, in which the author enlarged and corrected the results obtained by Peltier and De la Rive.—M. W. Fonvielle read an explanation of the appearance, during balloon ascents, of rings which do not exhibit chromatic decomposition.—A letter was read from M. de Bizeau, of Entre-Monts, near Binche, in Belgium, giving the extreme cold at that place on the 8th December, 1871, at -21.5° C. (= -6.7° F.) at half-past 7 A.M.—M. Pasteur presented a note upon a previous communication of M. Trécul on the origin of lactic and alcoholic ferments, in which he stated that he saw nothing in M. Trécul's results to impugn the exactitude of former experiments or the conclusions which he had drawn from them.—M. A. Trécul read a paper, in which he described the cells of beer-yeast becoming mobile like monads.—M. Berthelot communicated a further paper on the state of bodies in solutions, in which he treated of certain salts of peroxide of iron (sulphate, nitrate, and acetate).—M. Balard presented a third note by M. C. Saint-Pierre on the spontaneous decomposition of certain bisulphites (of lead and baryta).—M. Robin communicated a note by MM. Rabuteau and Massul, on the physiological properties and metamorphoses of the cyanates in the organism, in which the authors state as the result of their researches that the cyanates of potassa and soda are not poisonous, and that in the animal economy they give origin to carbonates.—A note by M. S. Jourdain, containing materials towards the history of *Gymnetrus gladius*, was presented by M. Blanchard. The author describes the anatomy of a specimen of this rare fish, which was stranded near Palavas (in Hérault).—A note on the heat absorbed during incubation by M. A. Moitessier was communicated by M. Balard. The author finds that the specific heat of fecundated is less than that of unfecundated eggs when treated in the same manner, and infers that a portion of the heat absorbed by the former during incubation is transformed.—M.

Décaille presented a note by M. A. F. Marlon on the fossil plants of Ronzon in the department of the Haute Loire. The flora of the marly limestones of Ronzon includes only fifteen species belonging to the same number of genera; eleven of the species are said to be new. These belong to the genera *Equisetum*, *Polostachys*, *Myrica*, *Celtis*, *Litsaea*, *Bumelia*, *Myrsine*, *Pistacia*, *Mimosa*, *Echeitium*, and *Rovnoacarpum*. The facies of the flora is African or Asiatic.—A note by M. Bleichen on the discovery of *Posidonia minuda* in the Trias of the department of the Gard, and on a deposit of schists containing *Valchia* in the Permian formation of Aveyron, was presented by M. de Verneuil; and a note by M. Sanson on an equine skull from the turbaries of the Somme by M. de Quartrefages. The author of the last-mentioned paper refers the skull obtained by Boucher de Perthes from the ancient turbaries of the Somme to the African variety of the common ass.

January 8.—M. Martin de Brettes presented a memoir on the motion of oblong projectiles in resisting media, and on the explanation of the wounds produced in living creatures by the oblong balls of rifled guns.—M. E. Rolland read a memoir on the effects of variations of work transmitted by machines, and on the means of regulating them.—Three letters from M. Janssen were read, giving an account of the position selected by him at Sholor, in Neigherry Hills, for the observation of the solar eclipse of Dec. 12, and a brief statement of his results, the latter will be found in another column.—M. S. Meunier read a note on the transition types in meteorites. In this paper the author indicated certain transitions between the constituents of meteorites analogous to those occurring in terrestrial lithology—namely, between lucite and montrejte, mesminite and canellite, montrejte and lime-richtite, montrejte and stawoopolite, and between aumalite and tadjente.—A memoir was presented by M. C. A. Valsen on a relation between capillary actions and densities in saline solutions, in which he showed by a table of results that in nearly all cases the amount of capillary action is dependent on the density of the fluid.—M. H. Sainte-Claire Deville presented a note by MM. Troost and P. Hautefeuille on the action of heat upon the oxy-chlorides of silicium.—M. Berthelot read the conclusion of his memoir on the state of bodies in solutions, which related to persalts of iron.—M. S. de Luca communicated some investigations of a complex alum, obtained from the thermomineral water of the Solfatara of Puzzuoli; it consists of sulphuric acid combined with alumina, ammonia, protoxide and sesquioxide of iron, lime, magnesia, and potash, with traces of soda and manganese.—A note by M. D. Tommasi on the action of iodide of lead upon some metallic acetates was read.—M. Dubrunfaut presented a note on the combustion of carbon in carbonic acid in pre-ence of water, in which he indicated the importance of the presence of aqueous vapour in many phenomena of combustion. M. Dumas spoke in opposition to the views of Dubrunfaut.—M. Pasteur communicated a note by M. J. C. de Seynes on the asserted transformations of Bacteria and Mucedineæ into alcoholic ferments; and M. F. Béchamp a paper on the development of alcoholic and other ferments in fermentescible media, without the direct intervention of albuminoid substances.—M. Boussingault presented a note on saccharine matter which appeared in the leaves of a lime tree.—The author stated that the saccharine fluid observed by him was not, as is generally supposed, the production of *Aphides*, but apparently a morbid secretion of the tree; it was found to be identical in saccharine constitution with the manna from Sinai analysed by Berthelot.—M. C. Dareste read a note in which he described the presence of bodies presenting the characters of starch-grains in the testes of birds, before the appearance of the spermatozooids.—M. Decaisne presented a note by M. J. E. Planchon, on the characters and systematic position of the Chinese spiny elm (*Hemiptera Davidii*); and M. Daubrée some observations by M. H. Magnan, on two recent notes by M. Cayrol, on "The Lower Cretaceous formation of La Clape and Les Corbières."

BOOKS RECEIVED

ENGLISH.—Text Books of Science: Arithmetic and Mensuration: C. W. Merrifield (Longmans)—The Elements of Plane Geometry, 2nd edition: R. P. Wright (Longmans)—Concerning Spiritualism: Gerald Massey (Burns)—Catalogue of Transactions, &c., Radcliffe Library, Oxford.

AMERICAN.—Approved Plans and Specifications for Ports, Hospitals, &c.—Reports on Barracks and Hospitals, &c.—Elements of Chemistry and Mineralogy, Vol. II: J. Hinrichs.

DIARY

THURSDAY, JANUARY 18.

ROYAL SOCIETY, at 8.30.—Investigations of the Currents in the Strait of Gibraltar, made in August 1871, by Capt. Nares, of H.M.S. *Shearwater*: Admiral Richards, F.R.S.—On the Absolute Direction and Intensity of the Earth's Magnetic Force at Bombay, and its Secular and Annual Variations: C. Chambers, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.—On Neolithic and Savage Implements: A. W. Franks, M.A., and Col. A. H. Lane Fox.

CHEMICAL SOCIETY, at 8.

ROYAL INSTITUTION, at 9.—On the Chemistry of Alkalies and Alkali Manufacture: Prof. Odling, F.R.S.

LINNEAN SOCIETY, at 8.—On the Anatomy of the American King-Crab (*Limulus polyphemus*, Lat.): Prof. Owen, F.R.S. (Continued.)

FRIDAY, JANUARY 19.

ROYAL INSTITUTION, at 9.—On the new metal Indium: Prof. Odling, F.R.S.

SATURDAY, JANUARY 20.

ROYAL INSTITUTION, at 2.—On the Theatre in Shakespeare's Time: Wm. B. Donne.

SUNDAY, JANUARY 21.

SUNDAY LECTURE SOCIETY, at 4.—On King Arthur: the legend and its significance in relation to English life, past and present: Sebastian Evans.

MONDAY, JANUARY 22.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.

VICTORIA INSTITUTE, at 8.—On the Influence of Colloid Matters upon Crystalline Form: Dr. W. M. Ord.

ENTOMOLOGICAL SOCIETY, at 7.—Anniversary Meeting.

LONDON INSTITUTION, at 4. Elementary Chemistry: Prof. Odling, F.R.S.

TUESDAY, JANUARY 23.

ROYAL INSTITUTION, at 3.—On the Circulatory and Nervous Systems: Dr. W. Rutherford, F.R.S.E.

WEDNESDAY, JANUARY 24.

GEOLOGICAL SOCIETY, at 8.—On the Foraminifera of the family Rotulina (Carpenter) found in the Cretaceous formations, with Notes on their Tertiary and Recent Representatives: Prof. T. Rupert Jones, F.G.S., and W. K. Parker, F.R.S.—On the Infra-Lias in Yorkshire: Rev. J. F. Blake, F.G.S.—Further Notes on the Geology of the Neighbourhood of Malaga: M. D. M. d'Orqueta.

SOCIETY OF ARTS, at 8.—On Improvements in the Process of Coining: Ernest Seyd.

ROYAL SOCIETY OF LITERATURE, at 8.30.—On Excavations at the Site of the Homeric Pergamus: Dr. J. G. Von Hahn.

THURSDAY, JANUARY 25.

ROYAL SOCIETY, at 8.30.

SOCIETY OF ANTIQUARIES, 8.30.

ROYAL INSTITUTION, at 3.—On the Chemistry of Alkalies and Alkali Manufacture: Prof. Odling, F.R.S.

THURSDAY, JANUARY 25, 1872

THE SOLAR ECLIPSE

ACCOUNT OF OBSERVATIONS MADE AT POODOCOTTAH

THE spectral observations of recent total eclipses of the sun had plainly demonstrated the existence of an incandescent gaseous stratum or atmosphere, surmounting the chromosphere or stratum of hydrogen which envelops the body of the sun, but they had not sufficed to determine its true conformation and extent. This question, therefore, constituted one of the principal problems remaining to be solved by observations of the eclipse of the 12th of December, 1871.

The slit-spectroscope applied to large telescopes doubtless affords the best means of verifying the existence, in the circumsolar regions, of this gaseous stratum, which may be termed the superior chromosphere, and of determining the materials of which it is composed; but from the shortness of the time available in an eclipse, the spectroscope can furnish only partial and local results, insufficient, therefore, to reveal the true structure, form, and dimensions of this upper chromosphere.

Preceding observations having shown that the light of the solar corona is composed for the most part of a small number of elementary rays differing considerably in refrangibility, it appeared to me that the form and dimensions of the higher chromosphere might be much more conveniently studied by means of a large prism fixed in front of the object-glass of the telescope, whereby the several chromatic images of the corona would be distinctly formed in the focal plane. If the prism has but little dispersive power, and the eye-piece does not magnify too much, all the chromatic images of the corona may in this manner be observed simultaneously in the same field, and their form and dimensions directly investigated.

Towards the end of the year 1868, a small flint-glass prism was made for me by Signor Merz, of Monaco, to be fitted to the object-glass of the equatorial belonging to the Observatory of Campodoglio, for observations on the spectra of the stars; and this apparatus, in consequence of the dispersion of the prism, and the goodness of this prism and of the object-glass, was found to be admirably adapted for observing the eclipse in the manner just described.

The dispersion of the prism from the lines C to H of Fraunhofer is about $32'$; the free aperture of the object-glass is $4\frac{1}{2}$ French inches; the field of the telescope is about 1° , with a magnifying power of 40.

My conviction of the great advantages which would be afforded by this instrument in the observation of the approaching eclipse, induced me to carry it to India for that purpose; and I was glad to learn that Mr. Lockyer, the chief of the expedition, had in like manner resolved to observe the corona by means of a spectroscope without a slit, being persuaded that this would be the most convenient method of solving the questions relating to the corona itself. With this instrument, then, I prepared to observe the eclipse, proposing to myself the following problems:—

1. To ascertain whether, just before the beginning, and at the end of totality, the solar spectral lines are reversed—a phenomenon observed by Prof. Young in the eclipse of 1870.

2. Amidst the several chromatic images of the prominences, to observe especially whether the image given by the yellow line D^3 coincides with that of the lines of hydrogen gas.

3. To define the form and dimensions of the chromatic images of the corona.

The day before the eclipse, I delineated, by means of the direct-vision spectroscope applied to the telescope, the profile of the solar disc, in order to ascertain the state of the chromosphere at the several parts of the limb, and the protuberances existing there. But the picture did not come out with sufficient exactness, in consequence of the cloudy state of the sky, and the strong wind which prevailed throughout the day. This picture, however, clearly showed that both on the eastern and on the western limb, at the point where contact would take place between the lunar and solar discs in the total eclipse, the chromosphere was in that abnormal condition which is generally observed in the neighbourhood of solar spots.

The number of the prominences was, however, rather small, and their dimensions moderate; conditions which appeared to me to be favourable for the examination of the corona.

From the 5th to the 11th of December, the state of the sky at Poodocottah was somewhat variable; and generally, in the early hours of the day, great masses of mist and cloud predominated in the east, leaving but little hope in favour of our station for observing the eclipse. On the morning of the 12th, indeed, the sky was almost wholly covered with dense masses of mist and cloud, completely obscuring the sun till 7h. 53m., at which time the eclipse had already begun. Soon after this the sun was again covered with thick clouds, but fortunately they began to break a few minutes before totality, when the bright disc of the sun was already sufficiently reduced, and when consequently the time for observation was rapidly approaching.

To verify the phenomenon of the reversal of the spectral lines at the extreme edge of the sun, I had arranged the plane of dispersion at right angles to the edge at the point of second contact.

At thirty seconds before totality, the spectral image of the luminous crescent was already sufficiently weakened to allow of its observation by the naked eye without a dark glass; and it was then that the principal dark lines of the solar spectrum came out distinct, and even more strongly marked than before, and curved parallel to the bright edge of the sun; but a few seconds before totality these lines disappeared completely, and the spectrum became continuous, without however exhibiting, just before totality, the reversal of the lines, although I was watching most intently for this phenomenon. I would not, however, be understood as denying altogether the reversal of the lines, for it is not impossible that a thin film of mist, or the bright atmospheric light at that time diffused over the spectrum of the solar limb, may have concealed the bright lines.

At the very instant of totality, the field of the telescope exhibited a most astonishing spectacle. The chromo-

sphere at the edge which was the last to be eclipsed—surmounted for a space of about 50° by two groups of prominences, one on the right the other on the left, of the point of contact—was reproduced in the four spectral lines, C, D³, F and G, with extraordinary intensity of light and the most surprising contrast of the brightest colours, so that the four spectral images could be directly compared and their minutest differences easily made out.

In consequence of the achromatism of the object-glass, all these images were well defined, and projected in certain coloured zones, with the tints of the chromatic images of the corona. My attention was mainly directed to the comparison of the forms of the prominences on the four spectral lines, and I was able to determine that the fundamental form, the skeleton or trunk, and the principal branches, were faithfully reproduced or indicated in the images, their extent being, however, greatest in the red, and diminishing successively in the other colours down to the line G, on which the trunk alone was reproduced. In none of the prominences thus compared was I able to distinguish, in the yellow image D³, parts or branches not contained in the red image C.

Meanwhile the coloured zones of the corona became continually more strongly marked, one in the red corresponding with the line C, another in the green, probably coinciding with the line 1474 of Kirchhoff's scale, and a third in the blue perhaps coinciding with F.

The green zone surrounding the disc of the moon was the brightest, the most uniform, and the best defined. The red zone was also very distinct and well defined, while the blue zone was faint and indistinct. The green zone was well defined at the summit, though less bright than at the base; its form was sensibly circular and its height about $6'$ or $7'$. The red zone exhibited the same form and approximately the same height as the green, but its light was weaker and less uniform. The height of the green zone was estimated by comparison with the moon's diameter, and from the observed distance of the spectral lines of the prominences.

These coloured zones shone out upon a faintly illuminated ground, without any marked trace of colour. If the corona contained rays of any other kind, their intensity must have been so feeble that they were merged in the general illumination of the field.

Soon after the middle of the total eclipse, there appeared on the eastern limb, at about 110° from the north point, a fine group of prominences formed of jets rather low but very bright, some rectilinear, others curved round the sun's limb, and exhibiting the intricate deviations and all the characters of prominences in the neighbourhood of solar spots. The brightness and colour of these jets were so vivid as to give them the appearance of fireworks.

The spaces between some of these jets were perfectly dark, so that the red zone of the corona appeared to be entirely wanting there. Perhaps, however, this was only an effect of contrast due to the extraordinary brightness of the neighbouring jets. I have thought it right to refer to this peculiarity, because the appearance of interstices, or dark spaces, between prominences of considerable brightness, is often observed by means of the spectro-scope, independently of total eclipses.

The want of an assistant to note the time, and to write

down the observations as they were made, occasioned me some loss of time, and the end of the total eclipse was already at hand before I was aware of it.

The green and red zones were well developed at the western as at the eastern limb, while the blue remained faint and ill-defined. Soon after the appearance of the chromosphere at the western edge, there was suddenly projected on the spectrum of the sun's limb, which then appeared beyond that of the moon, a stratum of bright lines, separated by dark spaces; but I could not determine whether they were due to a general or partial reversal of the spectral solar lines, or to a simple discontinuity in the spectrum, since they were too soon immersed in a flood of light, which put an end to the totality of the eclipse.

About half an hour after the total eclipse, the sun was obscured by clouds, so that I was unable to observe the end of the partial eclipse.

Later in the day, when the sky had become sufficiently clear, I observed with the spectro-scope the state of the chromosphere, and of the protuberances existing upon it; but in consequence of the cloudy state of the sky, the violent wind which prevailed, and the shortness of the time at my command, the picture was not sufficiently distinct and detailed.

L. RESPIGHI

THE ZOOLOGICAL RECORD FOR 1870

The Zoological Record for 1870; being Vol. VII. of the "Record of Zoological Literature." Edited by Alfred Newton, F.R.S. (London: published by John Van Voorst, for the Zoological Record Association, 1871.) Pp. 523.

THE "Record of Zoological Literature" is already so well known to, and so well appreciated by, all students of zoology, that we need only remind our readers of the fact that, after five volumes had been published by Mr. Van Voorst, under the editorship of Dr. Günther, the publisher found it impossible to continue its publication, the actual yearly loss being something very considerable. It is true that the British Association for several years contributed 100*l.* towards this loss, and that three of the Recorders contributed, during the years that the British Association was so liberal, an equal sum out of their own pockets. Still, the expenses of such a work are so great, and the number of copies sold so small, that we were not surprised at Mr. Van Voorst's decision, nor to find that the present editor was compelled to look to the co-operation of zoologists generally to attain its continued publication; and it speaks much, not only for his energy, but also for the personal esteem with which he is regarded, that he could obtain in so short a time upwards of eighty friends who should guarantee 400*l.* between them towards any loss that might accrue on this, the seventh volume. While we do not pretend to be in the councils of the committee of the Zoological Record Association, nor have we received even so much as a hint on the subject from the secretary, yet we may venture to express our belief that the members, while they will have the consciousness of having furthered the publication of this work, will not have to pay very much more for the seventh volume than they had for each of the previous six.

Dr. Günther and M. E. von Martens are the only two of the original Recorders who take part in the production of this volume. Prof. Newton's section is taken by Messrs. Sharpe and Dresser; the Insecta are recorded by Messrs. Rye, Kirby, Verrall, M'Lachlan, and Scott; the Arachnida and Myriapoda are noticed by Mr. Cambridge; and the Worms and concluding orders by Mr. E. R. Lankester and Prof. Traquair. The editor stands up bravely in his preface for his staff, and we think he has a very good right to be proud of the work done by his assistants; though we somewhat fail to perceive "the new and perhaps improved modes of treatment" that he refers to.

In proceeding to offer a few friendly criticisms on this work, we would in the first place remark that both editor and Recorders deserve not only the thanks of the Association, but of all zoologists, for the excellent way in which they have accomplished their very difficult tasks, and that we trust that one and all of them will consider our comments as meant for suggestions, and not for fault-finding.

The two most novel features in the volume are "The List of Abbreviated Titles of Journals quoted," and "An Index to the Genera and Sub-genera Recorded as New." As to the List, until we looked over it, we confess that we had an idea that there was some law that guided one in abbreviating the title of a journal. The reader may, perchance, have looked over that corner of the journals of some of the Continental societies in which are recorded the various works sent to them in exchange; and if so he must have smiled to have seen the oftentimes funny attempts made to abbreviate the titles of the British societies. We promise him that, if ever he smiled on such occasions, he will smile still more when he just reads through the "concise forms of citation" given in the "Record," pp. 7-11; and he will, we think, exhaust his patience before he finds out on what principle these concise forms have been chosen. "Ibis" stands for "The Ibis;" while "J.F.O." stands for "Journal für Ornithologie," "P.L.S." stands, not for "Philip Lutley Sclater," as for a moment, in our innocence, we thought, but for "Journal of the Proceedings of the Linnean Society." While the "Journal of the Linnean Society" is very likely to be quoted in the future pages of the "Record," we fancy the "Proceedings" of the society—at least since 1867—will never more be referred to. Of course, any symbol might serve to indicate the journal of a society; but it is rather hard to compel a reader or a consulter of the "Record" to learn off some five pages of such before he can get along. The other novelty supplies a very great need, and one that we believe was often urged on the editor of the first series. The list of names of Genera and Sub-genera occupies in all but five pages, and we would suggest that a little additional space would, in future years, be well spent in indicating where, when, and by whom any of these names had been used before. In the present instance a symbol is affixed to some of the names, indicating that the name to which it is affixed has been used before. But the list has not been properly, or even very carefully, scrutinised for this purpose. On just reading it over, and without referring to such valuable indices as those published each year by the Zoological Society of London, or without pausing at names as familiar as household words to a botanist, we quote the following:—*Argyritis*, Hein.; *Brachyleptus*, Mots.; *Cad-*

mus, Theob.; *Ceratophora*, Hein.; *Chelaria*, Hein.; *Dorvillia*, Kent; *Eucharia*, Boisd.; *Eurypus*, Semp.; *Euteles*, Hein.; *Gonia*, Hein.; *Helleria*, Czern.; *Lamprotes*, Hein.; *Lucina*, Wlk.; *Pephricus*, Pasc.; *Perideris*, Fieb.; *Plicatella*, Sdt.; *Pœcilia*, Hein.; *Psammobates*, Günth.; *Rhinosisia*, Hein.; *Thysanodes*, Ramb.; *Trichocyclus*, Günth.; *Trinella*, Gray; *Zetobora*, Wlk.; as names all in previous use, not to say that a query might well be affixed to such as *Cephalobares*, Camb., as being too near to *Cephalobarus*, Schönk.; and if *Ceratonina*, Rond., is pronounced to resemble too closely *Ceratonia*, Harr., which, however, we do not quite see, then is there not greater danger of *Euplecta*, Semp., being confounded with *Euplectus*, Kirby? It is quite possible that some of these names may, though once used, have since fallen into disuse; and it is very probable that others in the list, unnoticed by us, may have been in use before. To be certain about this would take more time than is at our disposal; but we feel quite sure enough has been said to induce the editor to extend this valuable portion of the "Record," and to make it more exact in the next volume.

May we venture also to say that to certain zoologists who are in some measure ignorant of the mysteries of the Bird Regions, however important from an educational point of view the present arrangement of this part of the Record may be, it would be more generally useful if the titles of papers were all thrown into one series. This would at all events avoid the trouble of cross references, which savour too much of a library catalogue. When we come to the Mollusca, we find a novel practice which, as far as we can find, is not attempted among the Birds, and which we could not fancy being adopted by the Recorder of the other Vertebrates—viz., of not giving the pages on which the descriptions of new species are to be found. This is certainly a most mistaken economy of space, and very materially detracts from the value of these portions of the Record, for one great use of the Record is to enable one to quote an exact reference to a species the history of which one may be quite familiar with, and yet not have the volume containing that history at hand. There is, however, no uniformity in the matter in the present Record, and the Recorders that sin most in this result are those of the Mollusca, Crustacea, Arachnida, and among the Insecta, the Recorders of the Lepidoptera and of the Diptera.

We have been very much struck by the excellent way in which the Records of the Arachnida and Insecta have been executed, save that they too often quote from reprints. Mr. Cambridge and Mr. Rye's portions are quite models of such work. While we acknowledge the thoroughness of the work to be found in the Record of the Neuroptera and Orthoptera, we regret to see the criticisms on Mr. Walker's Catalogues, on p. 451. It is, we take it, not the province of a Recorder to indulge in such criticism, however well deserved it might be; and there are many who will remember how damaging such kind of remarks, made by a certain gentle entomologist, were to the Insect portion of Leuckart's "Bericht."

In his Record of the Vermes, Mr. Ray Lankester has neither done himself nor his subject justice. His mode of arrangement is novel and without precedent; but he has forgotten to give the number of pages to which each memoir extends, and, stranger still, he overlooks quoting

the new genera or species described, and this notably in the case of the last work of the illustrious Claparède, and again in the case of Van Beneden's memoir, where we are told, simply enough, that "a number of new and little-known cestoid and other parasitic worms are described and figured." A whole page is taken up with a list of the Annelids referred to in a paper by Prof. Grube, but the list is quite useless, as it wants the remarks as to their synonymy.

Prof. Traquair's portion of the Record appears to have been very well executed. We wish he had given us the list of the Echinoderms from the Dutch East Indies, as described by Herklots. It would have been much more valuable than the list given of very common species from the East Frisian coast; and although we notice an omission of a paper or two among a group (the Cœlenterates) somewhat familiar to us, yet this portion of the volume leaves very little to be desired.

No one individual could write an exhaustive criticism on such a work as this Zoological Record. We have not even attempted it. The moment the volume reached us we cut its pages, and in noting its contents the remarks that we have now made recurred to us; but in addition to these there was also present to us the thought of how much we owed for the successful publication of this work to its accomplished editor and his well-qualified and trusty staff of friends. E. P. W.

OUR BOOK SHELF

- I. *Earthquakes, Volcanoes, and Mountain-building*, three articles published in the "North American Review," 1869—1871. By J. D. Whitney. 8vo, pp. 107. (University Press, Cambridge, United States, 1871.)
- II. *Historical Notes on the Earthquakes of New England, 1638—1869*. By William T. Brigham, A.M., A.A.S. 4to, pp. 28. (Boston, 1871.)

THE first of these works is a small volume containing three reviews, or essays, as they might be more correctly termed, reprinted from the "North American Review," and written by the well-known geologist Mr. Whitney, formerly director of the Geological Survey of California. They are well worthy of perusal, not only from the easy, somewhat popular style in which they are written, but more especially from their containing a tolerably fair summary of the opinions held by most of the later scientific writers who have treated of the phenomena of earthquakes, volcanoes, and mountain-building, as it is here termed, drawn up by one who is evidently well-read in the literature of these subjects.

To give in its turn a summary of the author's opinions as far as we are able to understand them from a perusal of these three essays, we might state, in the first place, that he lays considerable stress on the geographical data, which show that the area within which the greater earthquakes have been mainly confined is also to a great extent coincident with that of the greatest displays of active volcanic forces; and on the observations showing the action which the moon, or rather of the sun and moon combined, exert on the number and intensity of earthquakes, which, if accepted, indicate an internal condition of fluidity in our globe; he believes both in the chronological succession of volcanic rocks, and in their having proceeded from some common or connected source within the earth, but does not agree with those who regard the access of water as the great agent in volcanic catclysms; disbelieving (in opposition to some elaborate calculations to the contrary) that the force capable of being developed

by steam at such immensely high temperatures, could be sufficient to account for the phenomena of ejection; and although admitting the proximity of volcanoes in general to the sea, points out that some of those in South and North America are situated inland, several hundred miles distant from the ocean.

Regarding the differences in texture between the granitic rocks and those of recent volcanic origin as due mainly to the different conditions of our globe in the early periods in which they were erupted, Mr. Whitney protests against the hypothesis, so much brought forward of late, that the former are merely sedimentary deposits, brought within the action of, and softened or liquened in, some unaccountable way by internal heat, and with respect to the origin of mountains, regards the external action of rain and rivers, now so all-absorbing in the minds of most English geologists, as altogether secondary to more powerful internal forces, believing, whilst mountain-building is to a great extent the result of an antagonism between subsiding and stationary masses of the earth's crust, that in all the great chains of mountains we have ample proof that this is at the same time accompanied by the intrusion of eruptive rocks from below, as a necessary consequence.

The second brochure by Mr. Brigham is reprinted from the memoirs of the Boston Society of Natural History; it appears to be the first part of a more lengthy communication to the Society, and is entitled "Volcanic Manifestations in New England;" it is an apparently exhaustive catalogue of all the principal earthquakes which have taken place, or rather been recorded, since the discovery and settlement of the country until the commencement of last year, bearing evidence of much industry, and appearing to be a valuable contribution to the records of American Seismology. D. F.

Astronomische Tafeln und Formeln. Herausgegeben von Dr. C. F. W. Peters, Assistant der Sternwarte in Altona. (Hamburg: W. Mauke, 1871; London: Williams and Norgate.)

A USEFUL collection of auxiliary astronomical tables compiled by the son of the well-known, editor of the *Astronomische Nachrichten*. It brings under one cover many tables for which the computer has ordinarily to resort to different books; and in some cases the tables are exhibited in a more expanded form than that in which they are usually printed. It contains copious tables for converting time into arc, sidereal into solar time, hour and minute intervals into decimals of the day, refraction and hypometrical tables, tabular data referring to the figure of the earth, tables of squares and trigonometrical functions, and many others for facilitating the reduction of astronomical observations. It has also a collection of formulae in common request, goniometrical, trigonometrical, and astronomical. The collection is based upon, and is in many respects closely similar to that made by Schumacher in 1822, and which was re-edited and enlarged by Warnstorff in 1845. Dr. Peters has, however, added many new tables, and modernised others where necessary. We could wish that a little more care had been bestowed upon the printing; the figures on some of the pages are very indistinct, and would tease a computer sorely. The defect is not accidental to a single impression of the work, for two copies have come before us, and in both the same pages are faulty. J. C.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Zoological Statistics and the Hudson's Bay Company

AMONG the "Notes" in NATURE of December 28, there is one in which mention is made of the great dearth of martens imported into London this last season from Hudson's Bay, also

of the death of 3,000 Indians from small-pox in the Saskatchewan district. It is then added "that martens that are not killed, and Indians that die, mean reduced dividends to the Hudson's Bay shareholders and traders."

Having lived a good many years in the Hudson's Bay Territory, perhaps you will permit me to mention a curious circumstance which I noticed, in illustration that martens may abound yet comparatively very few be killed.

In all parts of the fur country east of the Rocky Mountains, where there is timber, hares (*Lepus americanus*), or "rabbits," as they are commonly, but wrongly, called, are found in greater or less numbers, and they congregate in certain favourite localities. The Indian pitches his tent near one of these places, and by setting snares (which his wife and children attend to), easily supplies himself and family with food, whilst the skins of the hares are worked up into most comfortable blankets.

The hunter all the while is trapping the marten and other fur-bearing animals that assemble to prey upon the poor rabbits, and is thus enabled to secure without much labour a large and valuable stock of furs, chiefly martens.

The hares are, however, liable to a very fatal epidemic,* which usually attacks them when they have become very numerous, and they gradually die off, so that in two or three years there is scarcely one to be seen. This scarcity continues for a couple of winters or so, after which the hares again begin to increase, so that at periods of eight or ten years they are at their maximum.

During this dearth of hares, the Indian has to go to a fishery, or is obliged to travel about in search of buffalo, deer, or other game as a means of support, and has little time for trapping the marten; and if he had the time, he would still be under great disadvantage, for the marten, lynx, and fisher have also to scatter themselves all over the country to pick up a precarious living on lemmings, partridges, and other odds and ends, instead of feasting in luxury and ease, as they do, on the hares when abundant. Thus, when hares are numerous, many marten skins are obtained, when hares are few marten skins are also few, not necessarily because martens are scarce, but that they are difficult to get.

The death of even 3,000 prairie Indians in one season, however injurious it might be to the trade of the Hudson's Bay Company in other kinds of furs, would not particularly affect the number of marten skins obtained.

I may here record a striking instance of the efficacy of vaccination as a preventative of small-pox. Nearly forty years ago this dreadful disease spread like a scourge from the Missouri river all over the prairies, being carried by bands of horse-stealers from one tribe to another; for these amiable "children of nature" no sooner heard of any of their neighbours being attacked by the terrible disorder, than parties went immediately to rob the sufferers of their most valuable property. They got the horses, but they also caught the disease, and many hundreds died. The Crees, a tribe of many thousands, having nearly all been vaccinated by the Hudson's Bay Company's officer in charge of the district, escaped with the loss of only two of their number.

JOHN RAE

Ripples and Waves

THE article by Sir William Thomson upon Ripples and Waves in the November part of NATURE, which has just reached me, reminds me of a little capillary wave, the examination of which used to be a source of amusement to me some years ago; and as I have never seen any description of it, my observations may not be without interest to some of your readers.

I had long noticed this little wave, winding about, like a hair upon the surface, amongst the eddies which formed in a deep river below a considerable fall, which I used to frequent; but I first got an insight into its nature in a very different situation. I was in a canoe in a sheltered bay, with just enough wind overhead, without any ripple on the water, to make my canoe drift broadside on at the rate of, perhaps, half-a-mile an hour, when I saw my little wave formed about three feet in advance of the canoe. Being in the neighbourhood of a marsh the water was very impure, and the behaviour of the little particles floating in it attracted my attention. Any objects reaching to the depth of from an eighth to a quarter of an inch below the surface passed on to the canoe unaffected by it; but smaller particles were sud-

denly agitated on passing the wave, and after getting a few inches within it, they were arrested at distances varying with their size, the larger ones penetrating farther than the smaller ones. If the wind died away the wave was maintained at a greater distance from the canoe, and it was still perceptible at a distance of fully eight or nine feet from it, after which it became fragmentary and disappeared. If the pace of the canoe increased, the wave came nearer to it, and the particles, which had been brought to rest at various intervals according to their sizes, were driven up together, forming at last a sort of scum in advance of the canoe. If the wind increased suddenly, the wave disappeared, and the slightest ripple on the surface obliterated it at once; but if the wind freshened very gradually, the wave approached nearer and nearer, becoming at the same time more strongly defined, until it came to within about nine inches from the canoe, and was maintained there under its lee, even after there was breeze enough to make a considerable ripple outside. If pressed beyond that, ripples of quite another character would form just in advance of the wave, and it would break up, and the canoe would pass over the scum which had collected within it.

With this clue as to its nature, I frequently examined the wave in the situations where I had first seen it. Wherever there was any impediment to the stream, as a tree stretching out into it from the bank, there was the little wave ahead of it, at distances from the impediment varying with the force of the current. In the spring, when the water was high, a good deal of foam would be brought down from the falls above, and I would collect against these obstructions, but always leaving an inch or two of clear water within the wave. Upon clearing away the foam the wave would soon again be formed, and the next patch of foam which came down would experience a little jerk, as it passed the wave, and penetrate a few inches within it, when it would be arrested, and there would start out from underneath it little particles of sawdust, or other substances, which had been entangled in it, and would range themselves beyond it, in the order of their sizes. Presently more foam would come down, pushing on what had arrived before, till soon there would be an accumulation of it, as at first.

Where the wave was found winding about amongst the eddies there was no solid obstacle, but only one stream meeting another, and it was not at first sight easy to distinguish which was the front and which the back of the wave. The accumulation of scum, however, on one side showed this, and much more so the behaviour of the wave itself, according to the side from which you approached it. If you came down upon it with the stream, with your canoe broadside on, no effect was produced on the wave; but if you passed over it, it was almost immediately reformed on the other side. But if you approached it from the other side, you pushed it on before you; and by careful handling I have often succeeded in detaching a portion of the wave, and carrying it on before me for ten or fifteen yards; whilst after awhile another would be formed in the same place. Sometimes, where the water boiled up from below, there would be an irregular circular patch, surrounded by one of these waves, which you might drive up till the two sides met; or if you approached it stern on, you would cut the circular patch into two, in which case each would run up rapidly to their centre into a little conical jet, and if your pace was at all rapid there would be a drop projected upwards from it.

The wave is so minute that it was not easy to come to any conclusion as to its shape and size; but from the distorted reflection of an object held above it I satisfied myself that under ordinary circumstances it could not be more than one-twentieth of an inch high, the distortion not extending beyond half-an-inch on each side of the sharp cusp, and that it was convex towards the stream, with a very slight trace of concavity on the side of the obstacle generating it. It seemed as if the wave itself was a little elevated above the surface, and that it sloped back very slowly towards the obstacle. This is in accordance with the description above given of a narrowing circular patch running up to a jet; for, although the motion in that case was too rapid to permit of any precise observation, just before it closed in the patch had the appearance of a little table land elevated above the general surface. Upon one occasion, when a boom had been stretched across the river, running at the time fully five or six miles an hour, the wave was only about nine inches from the boom, against which a dense scum was collected, but still with about an inch of clear water between it and the wave. The wave in this case must have been fully an eighth of an inch high, and on its farther side were a succession of ripples, very much exceeding the capillary wave in height and amplitude, and differing

* It is quite as fatal in its effects as the grouse disease, and the causes are little known. The hares are found sitting in their forms dead. The Indians say they can tell when the disease is about to commence by a peculiar growth found in the abdomen.

from it in not being cusped, though otherwise imitating its general form.

It would appear, therefore, as if a wedge-shaped film of water were pushed ahead of the canoe, or other obstacle, the lower surface of which must, from the arrangement of the particles arrested, have been of rapidly-increasing curvature. Two difficulties, however, present themselves to this explanation—it is difficult to see how the film could have extended to the wave itself, as no particles, however small, appeared to be arrested within an inch or two of it; and my recollection is that upon the occasion of my first examining the wave driven before my canoe, light objects merely resting upon the water, like thistle down, seemed to be not at all affected by it, but to pass on towards the canoe unimpeded. Such objects, however, are so easily affected by the wind, or even the resistance of the air, that it was not easy to verify the observation.

Some other facts may be mentioned. The depth of the obstruction in the water seemed to have no sensible effect on the wave formed. Whether it was a log a foot through, or an inch board floating on the water, or whether it was the middle of the canoe drawing five or six inches, or the bow and stern barely touching the surface, the effect seemed almost the same. I have often, indeed generally, failed in my attempts to generate a wave with a canoe, and although upon the occasion when I first saw it so formed, I could trace it at fully eight feet from the canoe, I never found such a wave naturally formed at anything like that distance. The explanation appears to be that it requires very even and steady action to generate the wave; but that when once established it can be maintained under circumstances in which it would not be otherwise produced. As I stated before, if you approach it in one direction, you may take a canoe over it and it emerges on the other side unimpaired; the irregular currents of an eddy have no effect upon it except to give it an undulating motion, and I have seen it maintaining its place amongst the standing waves of a rapid when they have been several inches high. I have even raised considerable swells by rocking a canoe close to it, and it rides over them without disturbance; but the slightest ripple caused by the wind makes it disappear in a moment; and if spirits of turpentine be dropped on the water a little above it, the whole wave is instantly obliterated to a distance apparently far beyond that to which the oily film extends.

JOHN LANGTON

Ottawa, Canada, Dec. 28, 1871

The Rigidity of the Earth

ALTHOUGH, as he truly says, Sir W. Thomson's arguments for the rigidity of the earth have never been attacked, yet they have undoubtedly been too long ignored; and it is gratifying to see them asserted by their author in NATURE. Allow me, however, to remark on one sentence near the end of his quotation from the "Natural Philosophy," where Mr. Hopkins's observation is given, that the distribution of fluid matter within the earth is "probably quite local." Unless I am mistaken, Mr. Hopkins's opinion was, that its distribution is, as one might say, fortuitous. But, as I have elsewhere observed, the trains of volcanoes which accompany many of the great lines of elevation for enormous distances render the motion of such local distribution of fluid matter highly improbable, unless it be admitted that its presence is due to mountain elevations as a cause. I have suggested that this fluidity may arise from a diminished pressure beneath mountain ranges, owing to their mass being partly supported by the lateral thrust which has upraised them—a supposition which Mr. Scrope had already applied to account for an increased fluidity in the heated rock underlying a volcanic vent, when from any cause the pressure became less.

If any of your correspondents can propose another explanation of this remarkable coincidence compatible with the supposition of a rigid globe, it would be interesting to know it.

Hariton, Cambridge

O. FISHER

English Rainfall

IN reply to the letter of Mr. Vernon, in NATURE of the 18th inst., permit me to say that the confusion between the two *Seawater* is *his*, not *mine*. In the article to which he refers there is not a word about either Cockley Bridge or the Valley of the Duddon. His topographical knowledge of the districts is, apparently, as inexact as his manner of reading; for he does not seem aware that "the Styx," of which he speaks, is the

name, not of a *place*, but of a *rain-gauge*, in, as I said before, the immediate neighbourhood of Stockley Bridge.

J. K. L.

Circumpolar Lands

IN the last number of NATURE (Jan. 18), Mr. J. J. Murphy asks, "Can any mathematical reason be a signed why the contraction of the earth should be least in the direction of the polar direction? This would account for the rising of the land at the poles."

In the Proceedings of the Literary and Philosophical Society of Liverpool for Nov., 1857, there is a paper on a probable change in the earth's form, in which the rising of the land at the poles is inferred as a necessary result of the cooling and contraction of the earth.

The following is the substance, though not the exact words, of a portion of the paper; the precise words would not be intelligible without a diagram.

If a spheroid of equilibrium, in motion about an axis, contract uniformly in the direction of lines perpendicular to its surface, a new spheroid is produced, having a greater degree of eccentricity, because if equal portions are taken off the two diameters, the ratio of the equatorial to the polar diameter is increased. This is equivalent to a heaping up of matter around the equator in excess of what is due to the velocity of rotation, an increased pressure on the interior, in that region, must be produced, and a consequent transmission of pressure towards the poles. "A change of form is then necessary to restore equilibrium. This may not take place uniformly *per gradum*, for if there be a resistance from a rigid external crust, the force must accumulate until it exceeds the resistance, and thus frequent adjustments *per saltum* may ensue. It is probable, therefore, that the earth's form is undergoing a slow progressive change."

GEORGE HAMILTON

Queen's College, Liverpool, Jan. 21

The Kiltorkan Fossils

MR. BAILY's letter needs only a word or two from me.

I must protest against my reference to an error made by Mr. Baily being considered a "personal attack" upon him, or an "accusation" against him. Has Mr. Baily ever consulted a systematic work which did not contain corrections of the real or supposed errors of former workers? And did he consider such corrections as "personal attacks"?

On two points Mr. Baily has misunderstood or misread the plain statements of my letter:—1. I did not say that his drawing in "Explanation of Sheets 187, &c.," was made on the spot at Kiltorkan, but that it was a drawing of the fossil he had named *Sagenaria Veltheimiana*; 2. The qualifying phrase, "coal measure," was used, as it often is, as the equivalent of "carboniferous." How Mr. Baily could make it mean anything else perplexes me; seeing the Upper Carboniferous beds have no connection with the question. To have used it in the limited sense he suggests, and elaborately argues against, would have been absurd.

The remainder of Mr. Baily's letter is occupied with reference to private letters as evidence in the case. That written by Mr. Baily to Prof. Heer confirms the statement I made at the Geological Society, and repeated in your pages; but, in as far as it declares that the specimens sent to Prof. Heer from Kiltorkan were named *S. Bailyana*, it differs from the statement made by Prof. Heer at the Geological Society, who, on the evidence of these fossils, included *S. Veltheimiana* among the Kiltorkan fossils, and never mentioned *S. Bailyana*!

The reference to the other private letters is equally unhappy; for Mr. Baily is quite wrong in supposing my "accusation" was made because I could not persuade him to join me in work. My letter, if he will look at it again, bears a date some time after the "accusation" was made. And if at the same time he will read his reply, he will find that the reason he gave for declining to work with me is somewhat different from those he records in your pages. But the fact is, the letters have nothing whatever to do with my declaration, now more than ever confirmed by Mr. Baily's letter, that his giving to the Irish Lepidodendroid plant the name of a carboniferous species misled Prof. Heer. If Mr. Baily's letter indicates the "facts" contained in his paper, I can only conclude that it was the patriotism of your reporter that induced him to characterise them as "strong."

W. CARRUTHERS

Condurango

I HAVE read in No. 104 (October 26, 1871) of your scientific and highly-interesting journal, a few words on "Condurango," the new Ecuadorian plant that has lately called so much general attention in Europe and America to its supposed properties of curing cancer.

The want of exactitude in the description of the plant will doubtless give an erroneous idea of it to your readers, and with the desire of effacing such errors as those published in the "Andes" of Guayaquil, and in Bogorá by Mr. Buyon, to whom you make reference, allow me to present to you and your readers the botanical description of the Condurango twining plant, very useful, indeed, in some rheumatisms and secondary syphilitic disorders, but of very doubtful medicinal properties in cancer, so far as my own experience goes.

The Condurango belongs to the order *Asclepiadaceæ*, 3rd tribe, which corresponds to *Asclepias vera*; 1st division *Asclepius*, whose characters are that the limb of the corolla is without scales, and the stamens without appendage or corona.

This division comprehends only five genera, viz., *Mitostigma*, *Asclepius*, *Hemax*, *Hemipogon*, and *Nantonia*. In none of these genera can the Condurango be classed.

The genus *Mitostigma*, as a distinguishing character, has two long filaments at the end of the stigma, and this is not the case in Condurango. The genus *Asclepius* has the sepals acute, the corolla subcampanulate, and the stigma elongated; characters that do not belong to the Condurango. The genus *Hemax* has the divisions of the corolla hooded, and other characters not observed in the Condurango. The genus *Hemipogon* has the sepals of the calyx acute, hard, and with a curved extremity. The corolla is campanulate, which is not the case in Condurango. The genus *Nantonia* has the sepals striated and curved, which also is not the case in Condurango.

The flowers of the Condurango have a calyx of five divisions, obtuse, ovate, and villose in their inferior part, and of quincuncial præference. The corolla is rotate, of five divisions, lanceolate, hairy at the base on the inside, and somewhat fleshy, with a membranous margin. Its aestivation is imbricate. The stamens have no appendage or corona; the anthers are terminated by a membrane, and the pollen masses are elongated and suspended. The stigma is pentagonal and conical. The flowers are numerous, and disposed in umbelliferous inflorescence.

As aforesaid, the Condurango forms a new genus. It is absurd to speak of Condurango as it were the same as *Mikania huaco*.

In the importance of the subject I hope to find ample apology for asking room in your columns for these few lines.

A. DESTREGE

Guayaquil, Ecuador, Dec. 13, 1871

Ocean Currents

It appears to me that the numerical data adduced by Mr. Croll in his letter (NATURE, Jan. 11) disprove his conclusions.

The doing of 9 foot-pounds of work upon a pound of water should give it a velocity (in feet per second) of

$$\sqrt{2 \times 32 \times 9} = 24;$$

and the doing of one foot-pound of work upon a pound of water should give it a velocity of eight feet per second. These are much greater than the observed velocities, so that a margin is left for friction.

The following passage in Mr. Croll's letter also calls for some remark:—"But it must be borne in mind that the deflecting power of rotation depends wholly on the rate at which the body is moving. If difference of specific gravity be regarded as the impelling cause of any current, the deflecting power of rotation will certainly be infinitesimal."

The deflecting force does indeed vary directly as the velocity of the body acted on; but the curvature of path which the deflecting force tends to produce, is proportional to the quotient of the deflecting force by the square of the velocity, and therefore varies inversely as the velocity. In latitude 45°, a velocity of a foot per second would give a radius of curvature of less than two miles. Here, then, again, there is a wide margin left for resistance. The expression for the radius of curvature in feet, supposing that there are no resistances, is

$$\frac{6550 v}{\sin \lambda},$$

λ being the latitude, and v the velocity in feet per second.

Belfast, Jan. 13

J. D. EVERETT

Mock Sun

I THUS name the phenomenon I am about to describe, but without regard to scientific accuracy. Last evening, a little before sunset, I observed a dark bank of clouds crouched on the horizon, just beneath the sun, and a long mass of cirro-stratus above him. A band of light, of about half his width, stretched up and down to the clouds. This remained visible, with remarkable changes, till 25 min. after the sun's total immersion. On his disappearance the band gradually widened (or seemed to do so), and assumed the form of a table flower-vase, i.e., bulged at the base and cylindrical above. At ten minutes after sundown the band, which had been about 10' in length, stretched to 20', being superposed on the cirro-stratus, where it was rose-coloured, the bulged portion being orange. At twenty minutes after sundown a slight collapse occurred, and the band almost disappeared, the bulged portion becoming an orange disc, just like a second sun setting in fog. Soon afterwards this became elongated, and the band reappeared, stretching over an arc of 40°. A few minutes later all disappeared. I witnessed this beautiful phenomenon from a carriage on the L. and N.W. Railway, on both sides of Blisworth. C. M. INGLEBY

Edgbaston, Jan. 20

Solar Eruptions and Magnetic Storms

AT a recent meeting of the Astronomical Society a paper was read by Mr. Ranyard, in which some suggestions were put forward concerning the possibility of accounting for the solar prominences on the supposition that they may be caused by the projection of matter from a lower level, and that such an uprush into and through the layers above, emerging into the lighter envelope of the chromosphere, might lift before it a cone of compression of the gaseous matter, producing an elevation on the surface, visible to us as a prominence. And the solid particles or masses thus projected might form meteorites, the shape of the prominence being afterwards modified by other causes.

This theory, offering as it does a possible account of the genesis of prominences and meteorites, appears to contain the germ of another hypothesis respecting the cause of the connection between solar eruption and terrestrial magnetism.

If it be legitimate to suppose that in and near the photosphere we have a circuit of conducting matter (viz. incandescent metallic vapours), according to well-known facts any cause tending to effect an unequal distribution of heat, and at the same time a want of homogeneity of structure, such as a difference of pressure or density, would establish thermo-electric currents in such a circuit.

Now such a difference would arise from an upward burst of matter from below the photosphere. If, therefore, the prominences have their origin at great depths below the photosphere, we may expect currents of considerable intensity to circulate round the equatorial region of the sun. In the equatorial region rather than in any other, because it is there that the greatest disturbance is manifested, as shown by observations on the limits of spots and prominences; and, therefore, there that the necessary differences of temperature are most likely to occur, the effects of such currents being to create secondary or reduced currents in the adjacent layers, and, if of sufficient intensity, in the earth itself.

Provided that this be so, this supposition will suffice to reconcile some observed facts. Secchi has deduced,* in treating of the periodical variations of the magnetic elements, the law that "The annual disturbances are at a maximum at the equinoxes, and at a minimum at the solstices."

Knowing then that the plane of the sun's equator passes through the earth on June 11th and Dec. 12th, and that therefore the equator as seen from the earth presents its widest ellipse in March and September, it follows that such thermo-electric currents, if they exist, are able to exert their maximum inductive effect on the earth at or near the equinoxes.

The case is analogous to the experiment in which terrestrial magnetism is made to cause induced currents in a closed circuit rotated round an axis at right angles to the magnetic meridian.

In this case the ring is placed successively in positions variously inclined, but always keeps its plane perpendicular to the meridian, and the maximum induced current then occurs.

Similarly, solar equatorial currents would produce their maximum effect when the plane of the sun's equator has its aspect most nearly in the direction of the earth, and although any

* De La Rive's Electricity, tom. iii. p. 780.

variations in the intensity of these solar currents may be followed by a disturbance in the terrestrial magnetism at any time, yet such disturbance should be at a maximum at the equinoxes (as is the case by Secchi's law), because then the sun is most favourably situated for causing such effects.

In this hypothesis the source of the earth's permanent magnetism is not included, but simply the cause of the close connection between solar eruption and the disturbance of the terrestrial magnetic elements.

F. A. FLEMING

Mechanism of Flexion and Extension in Birds' Wings

UNDER the above heading in your issue of January 18, 1872, Dr. Elliot Coues describes the peculiar movements made by the bones of the wing of the bird in flexion and extension. It may interest some of your readers to know that those movements were minutely described and elaborately illustrated in a paper by Dr. J. Bell Pettigrew, communicated to the Linnean Society in June 1867, and published in vol. xxvi. of the Transactions of that body.

MILLEN COUGHTREY

Edinburgh University, Jan. 22

Elisée Reclus

A MEMORIAL addressed to the "Commission des grâces," sitting at Versailles, and most influentially signed by many of the leading scientific men in London, was presented at Versailles on the 3rd inst.

It is an appeal for commutation of sentence of deportation passed on Elisée Reclus, the well-known French geographer, author of "La Terre," an admirable popular work on physical geography (now being introduced as an English work* by Messrs. Chapman and Hall), and various other books.

A paragraph having appeared in several of the daily papers announcing that M. Reclus's sentence had been already commuted to simple banishment, I regret to state that he is still a prisoner at Versailles, although it is hoped the appeals made in his favour may produce the desired result.

The petition to the Commission in favour of Elisée Reclus was signed by the president of the Geological Society (Mr. Prestwich), Sir Charles Lyell, Bart., Mr. G. Poulett Scrope, Profs. Owen, Ramsay, Williamson, Duncan, Atkinson, Morris, Rupert Jones, Tennant, Messrs. Evans, Forbes, Gwyn Jeffreys, Drs. Carpenter, Richardson, and many others.

A second petition signed by Sir Henry Rawlinson, Sir John Lubbock, Bart., Mr. Darwin, and other men of eminence, was addressed to M. Thiers in favour of Elisée Reclus.

Surely the time for an amnesty has arrived.

British Museum, January 23

H. WOODWARD

NOTES ON MICROSCOPY

MOUNTING IN GLYCERINE.—It is often found desirable to mount very thin objects in glycerine, for which no special cell is requisite, and in which the thickness of a cell would be a disadvantage. To accomplish this was often a work of difficulty, since the presence of the smallest amount of glycerine outside the thin glass cover prevented the adhesion of the luting by means of which the cover was to be secured to the slide. Since the introduction of gum dammar dissolved in benzole to the attention of microscopists, this disadvantage has almost wholly vanished. It is now comparatively easy to mount such objects in the following manner. A small drop of glycerine, just enough for the purpose, is let fall in the centre of an ordinary cleaned slide, the object is then placed in the glycerine, having been previously soaked in benzole if any difficulty was likely to be experienced on account of contained air; a cover (say three quarters square) of thin glass is placed over the object and pressed down, taking care that the object remains in the centre; a wire clip then applied holds the cover in its place. If too much glycerine has been used, blotting-paper or a camel-hair pencil will remove all that issues beyond the edge of the cover. If too little, the

addition of more at one edge will supply the deficiency, and the superfluous remainder may be wiped away. Thus secured by the clip the edges of the cover may be painted round with gum dammar in benzole, and when dry and firm (in a day or two) the clip may be removed, and the surface of the slide carefully washed to remove any trace of glycerine. The clip may be replaced, and a second thin coating of dammar laid over the first, or old gold size may be used instead. When this is dry "papering" the slide in the usual way helps to provide against accident. The advantages derived from the use of this method are chiefly the facility with which the cover is attached, notwithstanding the presence of a trace of glycerine on the slide and cover, which it is not easy to avoid; and, so far as the experience of two years can vouch, freedom from leakage afterwards, especially when covered with paper. This plan succeeds best with objects as thin as the minute spores of fungi, delicate hairs, &c., and a one-eighth objective may be employed in their examination.

THE ASCI IN PEZIZA.—Having left a specimen of *Peziza hirsuta* for a long time in water until it became quite soft and pulpy, I was curious to examine it in such condition, and found that the hymenium presented a singular appearance. All the paraphyses had become dissolved into a granular mass, retaining still some of their original colour. Amongst these the asci were free, and there were some free sporidia. In their normal condition the asci are cylindrical, and the sporidia are arranged in a single series, but in the present case the asci had become perfectly spherical, from the absence of all lateral pressure, and the sporidia were clustered in the centre. The line of the external surface of the asci was very distinct amongst the orange-tinted granular mass, and the eight sporidia could be counted within. There could be no doubt of the presence of an investing membrane, but of a much more elastic nature than has been supposed. This fact seems to suggest the probability that more or less lateral compression in the hymenium may influence the character of the asci, and that cylindrical, or clavate and elliptical asci, indicate more or less of lateral pressure during development.

SACRED THREAD.—The sacred thread, or at least one kind of thread held sacred to religious purposes by the Brahmins in India, is derived from the stem of a species of water lily—some say the *Nelumbium speciosum*, others *Nymphaea edulis*. At any rate under the microscope it exhibits a mass of spirals, unwinding in ribbons of four or five threads laterally united. There is no trace of cells mixed up with it, and the spiral threads are as clean as if they had been removed with special care for microscopical purposes.

HOP MOULD.—A new mould has made its appearance during the past autumn on the spent hops so common about Burton-on-Trent. It formed large dense patches of a bright salmon colour, sometimes several inches in length and breadth, upon the sombre hops, and could not have escaped notice had it appeared in previous years. The structure of this mould seems to be closely allied to that of *Oidium*, whilst in many respects it reminds one of *Sporonema caci*. The creeping mycelium gives rise to branched threads, which become divided into strings of oval conidia or spores. The mould refuses to develop itself artificially, so that the mode in which the beaded spores were produced was not absolutely determined. Directly the threads come in contact with fluid of any kind they are resolved into a mass of oval cells or spores. Specimens of this mould have been published and distributed in Cooke's "Fifth Century of British Fungi" under the name of *Oidium aurantium*, a rather unfortunate specific name, since another member of the same genus which appeared nearly simultaneously on the Continent has been called *Oidium aurantiacum*.

* Sections I. and II. of this work are already published; Sections III. and IV. are now in the press.

HUXLEY'S MANUAL OF THE ANATOMY
OF VERTEBRATED ANIMALS*

THIS long-expected work will be cordially welcomed by all students and teachers of Comparative Anatomy, as a compendious, reliable, and, notwithstanding its small dimensions, most comprehensive guide in the subject of which it treats.

To praise or to criticise the work of so accomplished a master of his favourite science would be equally out of place. It is enough to say that it realises in a remarkable degree the anticipations which have been formed of it; and that it presents an extraordinary combination of wide, general views, with the clear, accurate, and succinct statement of a prodigious number of individual facts. The extreme brevity, indeed, takes one in some degree by surprise; and it is only on repeated reading that one feels assured that the facts exposed have been stated with sufficient fulness.

It is a wholesome and encouraging sign of the scientific literature and teaching of the day, that men of the highest eminence devote a portion of their time to the composition of elementary manuals or short guides in their respective sciences. The abuses to which such short manuals are subject are well known, and have been often commented on; and they are no doubt serious when leading to the formation of imperfect knowledge and the exclusion of more extended study. The objections, however, have weight chiefly as applied to the inferior class of such treatises, which, certainly, have too much abounded in this country. A thoroughly good manual, even though strictly elementary, besides forming the first secure basis of correct knowledge, excites a desire for fuller reading, and serves at later periods for useful revival of more complete information; while its small size obviously places it within the reach of many whose means do not enable them to become possessed of larger treatises, and has thus considerable influence in extending the study of the branch of science to which it is related.

Nor is Prof. Huxley's manual so very short as might at first be supposed from the unpretending form given to it; but rather the abundance of facts is surprising which the author has contrived to compress into the space, without any loss of that clearness and comprehensiveness of statement for which he is so well known. The amount of printed matter, indeed, is very nearly the same as that comprised in the portion devoted to vertebrate animals in the second edition of Gegenbaur's "Outlines," the most approved recent German elementary treatise on Comparative Anatomy.

It is also deserving of note that there is an entire absence of speculation and theory, as well as of any vague generalities. The words "teleology," "design," "type of organisation," "descent," "natural selection," "genesis of species," find no place in this manual, which deals simply with ascertained facts and principles. In most instances, where uncertainty prevails, the grounds of doubt are stated, or the subject is altogether omitted; but on the whole, as is perhaps right in a manual, the author leans to the side of positive statement of his own views, when he has made up his mind on any disputed point.

So much for the manner of the book. As regards the matter, it may be said that, while it presents a masterly and decided statement of the great principles of Vertebrate Morphology, the most characteristic and important feature which pervades the whole, is the constant reference of all anatomical description and zoological distribution to the facts and laws of organogenesis, as ascertained from the observation of fetal development. This is well known to be one of the great merits of Prof. Huxley's researches and writings, and he has made it

truly the key-note and whole tenor of the manual, so as assuredly to prove one of its most valuable qualities in its future influence on the study of Comparative Anatomy.

The first two chapters of the manual, extending to one hundred and eleven pages, are devoted to an exposition of the general organisation of the Vertebrata, as exhibited in the skeleton (endoskeleton and exoskeleton), the muscular system, the nervous system with the organs of sense, the alimentary canal including the teeth, the sanguiferous and lymphatic systems, the respiratory organs, and the renal and reproductive organs. This is premised by a statement of the distinctive characters of the vertebrate organisation, in which the double cavity of the body, neural and visceral, is taken as the most marked basis of distinction between vertebrate and invertebrate morphology; and a clear short sketch is added of the most prominent phenomena of fetal development.

The remaining six chapters contain a systematic exposition of the classification, organisation, and distribution of the several classes of vertebrate animals, under the three provinces of 1, Ichthyopsida, 2, Sauropsida, and 3, Mammalia; thus recognising the important approximations now established between Fishes and Amphibia under the first, and between Reptiles and Birds under the second of these provinces. In each class the position and organisation of extinct and fossil animals is also given.

The third chapter begins with the statement of the anatomical characters of the three great provinces; after which the organisation of fishes is described under an arrangement which is a modification of Johannes Müller's in the following groups, viz., I, Pharyngobranchii (Amphioxus); 2, Marsipobranchii (the Myxines and lampreys); 3, Elasmobranchii (the sharks and rays); 4, Ganoidei (Lepidosteus, sturgeons, &c.); 5, Teleostei (osseous fishes); and 6, Dipnoi (Lepidosiren, transitional).

In Chapter 4 the structure of the class Amphibia is similarly given, under the following distribution—viz., I, Saurobatrachia, including, 1, Proteida (Siren, Axolotl, &c.), 2, Salamandrida (newts, &c.); II, Labyrinthodonta; III, Gymnophiona (Caecilia, &c.); and IV, Batrachia (Anura, frogs and toads).

In Chapter 5, after giving the distinction between Reptiles and Birds as included under the province of Sauropsida, the class Reptilia is distributed under the following groups—viz., I, Chelonina; II, Plesiosauria; III, Lacertilia; IV, Ophidia; V, Ichthyosauria; VI, Crocodilia; VII, Dicotylodonta; VIII, Ornithoscelidia (Megalosaurus, Iguanodon, &c., transitional); IX, Pterosauria (Pterodactyles); and the comparative osteology of these groups is described.

In Chapter 6 Birds are distributed, and their Osteology is described under the following classification—viz., I, Saurura (Archæopterygidae, the metacarpals not ankylosed together); II, Ratidæ, including birds with more or less rudimentary wings, and in which the sternum is without a keel; III, Carinata, the large tribe in which the sternum is keeled, including four groups, viz., 1, Tinamomorphæ (Tinamous), 2, Schizognathæ, (the Plovers, Gulls, Penguins, Cranes, Hemipods, Fowls, Sand Grouse, Pigeons, Hoazin); 3, Ægithognathæ, (the Passerines, Swifts, and Woodpeckers); 4, Desmognathæ (the Birds of Prey, Parrots, Cuckoos, Kingfishers, Anserinæ, Flamingoes, Storks, Cormorants).

In Chapter 7 the Muscles and Viscera of the Sauropsida are described together.

Chapter 8 (180 pages) is devoted to the Mammalia, distributed in three great groups, as follows:—

I. Ornithodelphia (1, Monotremata).

II. Didelphia (2, Marsupial animals).

III. Monodelphia, divided provisionally into twelve orders as follows—3, Edentata, 4, Ungulata, 5, Toxodontia, 6, Sirenica, 7, Cetacea, 8, Hyracoidæ, 9, Proboscidea, 10, Carnivora, 11, Rodentia, 12, Insectivora, 13, Cheiroptera, 14, Primates. The first of these twelve orders is separated

* "A Manual of the Anatomy of Vertebrate Animals." By Thomas H. Huxley, LL.D., F.R.S. (London: J. and A. Churchill, 1871.)

viz., *a*, Cynomorpha (with ischial callosities), and *b*, Anthropomorpha. In this last the author recognises with certainty as distinct the genera Hylobates or Gibbons, Pithecus or Orang, and Troglodytes or Chimpanzee, and is inclined to separate Gorilla as a fourth genus.

FIG. 5.—A diagram intended to show the manner in which the aortic arches become modified in the series of the Vertebrata.

- A. A hypothetically perfect series of aortic arches, corresponding with the nine postoral visceral arches, of which evidence is to be found in some Sharks and *Marsipobranchii*. A.C. Cardiac aorta; A.D. Dorsal or subvertebral aorta. 1-IX, the aortic arches, corresponding with *Mn*, the mandibular; *Hy*, the hyoidean, and *Br.1-Br.7*, the seven branchial visceral arches. 1. II. III. IV. V. VI. VII., the seven branchial clefts. The first visceral cleft is left unnumbered, and one must be added to the number of each branchial cleft to give its number in the series of visceral clefts.
- B. Hypothetical diagram of the aortic arches of the shark *Heptanchus*, which has seven branchial clefts. S.A. The remains of the first visceral cleft as the spiracle. Branchiae are developed on all the arches.
- C. *Lepidosteus*.—The first arch has disappeared as such, and the first visceral cleft is obliterated. Internal branchiae are developed in connection with the second, fifth, sixth, and seventh aortic arches; external branchiae in connection with the fourth, fifth, and sixth. P.A. the pulmonary artery. The posterior two visceral clefts are obliterated.
- D. A Teleostean Fish.—The first aortic arch and first visceral cleft are obliterated, as before. The second aortic arch bears the pseudo-branchia (*Ps. B.*), whence issues the ophthalmic artery, to terminate in the choroid gland (*Ch.*). The next four arches bear gills. The seventh and eighth arches have been observed in the embryo, but not the ninth, and the included clefts are absent in the adult.
- E. The Axolotl (*Siredon*), a perennibranchiate amphibian. The third, fourth, fifth, and sixth aortic arches, and the anterior four branchial clefts, persist. The first visceral cleft is obliterated.
- F. The Frog.—The three anterior aortic arches are obliterated in the adult. The place of the third, which is connected with the anterior external gill in the tadpole, is occupied by the common carotid and the *rete mirabile* (carotid gland, *Ca.G.*) which terminates it. The fourth pair of aortic arches persist. The fifth and sixth pair lose their connection with the subvertebral aortic trunk, and become the roots of the cutaneous and pulmonary arteries. The first visceral cleft becomes the tympanum, but all the others are obliterated in the adult.

An interesting synopsis is given of the anatomical peculiarities of these animals, and of the circumstances in which they most differ from, or resemble, man. Among these the author has inadvertently overstated the propor-

tion of the volume of the brain of the orang and chimpanzee to that of man, when he rates it at about half the minimum size of the normal human brain. Taking thirty-three ounces as the lowest weight of the latter consistent with a natural condition in the adult male, the brain of the orang and chimpanzee may be stated at a third of that weight.

At p. 487 this subject is summed up as follows:—"Of the four genera of the Anthropomorpha, the gibbons are obviously most remote from man, and nearest to the Cynopithecini.

"The orangs come nearest to man in the number of the ribs, the form of the cerebral hemispheres, the diminution of the occipito-temporal sulcus of the brain, and the ossified styloid process; but they differ from him much more widely in other respects, and especially in the limbs, than the gorilla and chimpanzee do.

"The chimpanzee approaches man most closely in the character of its cranium, its dentition, and the proportional size of the arms.

"The gorilla, on the other hand, is more man-like in the proportions of the leg to the body, and of the foot to

FIG. 6.—A, the stomach of a Sheep. B, that of a Musk-deer (*Tragulus*). *a*, œsophagus; *Ru.*, rumen; *Ret.*, reticulum; *Ps.*, psalterium; *A.*, *Ab.* abomasum; *Du.*, duodenum; *Py.*, pylorus.

the hand; further, in the size of the heel, the curvature of the spine, the form of the pelvis, and the absolute capacity of the cranium."

The work is concluded with a brief statement of the characteristics of the human organisation. Among these the superior size of the head of the male infant at birth might perhaps have received a more prominent place. The short statement of variations in structure connected with difference of race is of peculiar interest. The various races of mankind are placed in two groups according to the character of the hair, viz., *a*, the Ulotrichi (crisp or woolly-haired), who are almost all dolichocephali, and *b*, Leiotrichi (straight-haired), who are distributed in four sets, viz., 1, Australoid, 2, Mongoloid, 3, Xanthochroic, or blue-eyed whites, and 4, Melanochroic, or dark whites.

It will now be proper to place before the reader some illustrations, taken from the "Manual," of Prof. Huxley's mode of treatment of individual topics.

The first of these which is selected (Fig. 1) relates to the intricate but deeply interesting subject of the homology of the *os quadratum* of birds and reptiles, a bone which was

compared by Cuvier to the tympanic bone of mammals, but which more lately, in consequence of the embryological researches of Reichert and Rathke, was held to correspond rather with the *incus*,—a view in which Prof. Huxley formerly concurred. Later observations, however, (detailed in a paper published in the Proceedings of the Zoological Society for 1869) have led him to alter his opinion, and to form the opinion that the *os quadratum* may, with the greatest probability, be regarded as representing the malleus.

In explaining this morphological point, Prof. Huxley refers as follows (at p. 27) to the osteogenetic process connected with the formation of the lower jaw and hyoid bone, or mandibular and hyoid arches.

"Two ossifications commonly appear near the proximal end of Meckel's cartilage, and become bones moveably articulated together. The proximal of these is the quadrate bone found in most vertebrates, the malleus of mammals; the distal is the *os articulare* of the lower jaw in most vertebrates, but does not seem to be represented in mammals. The remainder of Meckel's carti-

lage usually persists for a longer or shorter time, but does not ossify. It becomes surrounded by bone, arising from one or several centres in the adjacent membrane, and the ramus of the mandible thus formed articulates with the squamosal bone in mammals, but in other vertebrata is immovably united with the *os articulare*.

"Hence the complete ramus of the mandible articulates directly with the skull in mammals, but only indirectly, or through the intermediation of the quadrate, in other vertebrata. In birds and reptiles, the proximal end of the quadrate bone articulates directly (with a merely apparent exception in Ophidia), and independently of the hyoidean apparatus, with the petrotic capsule. In most if not all fishes, the connection of the mandibular arch with the skull is effected indirectly, by its attachment to a single cartilage or bone, the *hyomandibular*, which represents the proximal end of the hyoidean arch."

This last "is often united, more or less closely, with the outer extremity of the bone, called *columnella auris*, or *stapes*, the inner end of which, in the higher vertebrata, is attached to the membrane of the *fenestra ovalis*."

FIG. 7.—THE SKELETON OF THE HORSE.

A fuller and most interesting account of the origin and relations of these bones in connection with the changes occurring in the development of the first and second visceral arches, and with the formation of the external and middle parts of the ear is given at pp. 83—85; but there is only space here to reproduce the diagrammatic figure of the Manual (Fig. 2), which places very clearly in comparison their probable homology in fishes, reptiles, and mammals.

The main point on which the question hinges seems to be the separate connection ascertained to exist between the petrotic capsule and the two rods contained respectively in the first and second visceral arches; the proximate part of the first becoming the *quadrate bone*, or *malleus*; that of the second becoming the *incus* in the part above the attachment of the *stapes* to the rod, and *stapedius* muscle below; while the *stapes* itself, or *columnella auris*, is an offset, as it were, from the second rod proceeding to the *fenestra ovalis*. The subject, however, is one of so great difficulty, especially as connected with the existence and relations of the tympanic bone in birds and reptiles, to the proof of which the researches of Peters have been directed, that it would be hazardous to attempt any decision of the question at issue without

an opportunity of going very fully and minutely into the whole investigation.

The third illustration from the earlier part of the Manual (Figs. 3, 4) gives a clear view of the relations now very generally recognised between the rudimentary parts of the fetal brain and those forming the adult encephalon of the different classes of *Vertebrata*; and it is enough to refer to the diagrammatic figures, with their description.

The exposition which follows of the modifications in the form and organisation of the brain in different animals, together with the comparative views of the brains of the rabbit, pig, and chimpanzee, in figs. 21 and 22 of the Manual, is most instructive and worthy of attentive study.

The next illustration extracted from the Manual (Fig. 5) is diagrammatic, like the preceding ones, being intended to explain the changes by which, in fishes and amphibia, the permanent arterial vessels nearest the heart are derived from the common typical aortic arches, which, in the fetus of all vertebrate animals, surround the first part of the alimentary canal.

The illustration might advantageously be extended to show the parallel changes in reptiles, birds, and mammals; these, however, may be better given from the ventral than from the lateral aspect.

The figure here inserted of the skeleton of the horse (Fig. 7) is a very good example of the wood engraving, in which, notwithstanding the small scale, there is remarkable clearness of detail; and the succeeding figures, representing several details of the osteology of the same animal, are all to be commended for beauty and delicacy of execution.

The illustration given in Fig. 6 is one in explanation of the structure of the stomach of the ruminant, in connection with which the following statement of recently-established points regarding rumination may be quoted (p. 381):—

"1. Rumination is altogether prevented by paralysis of the abdominal muscles, and it is a good deal impeded by any interference with the free action of the diaphragm.

"2. Neither the paunch nor the reticulum ever becomes completely emptied by the process of regurgitation. The paunch is found half full of sodden fodder, even in animals which have perished by starvation.

"3. When solid substances are swallowed, they pass indifferently into the rumen or reticulum, and are constantly driven backwards and forwards, from the one to the other, by peristaltic actions of the walls of the stomach.

"4. Fluids may pass either into the paunch and the reticulum, or into the psalterium, and thence at once into the fourth stomach, according to circumstances.

"5. Rumination is perfectly well effected after the lips of the œsophageal groove have been closely united by wire sutures.

"It would appear, therefore, that the cropped grass passes into the reticulum and rumen, and is macerated in them. But there is no reason to believe that the reticulum takes any special share in modelling the boluses which have to be returned into the mouth. More probably, a sudden and simultaneous contraction of the diaphragm and of the abdominal muscles compresses the contents of the rumen and reticulum, and drives the sodden fodder against the cardiac aperture of the stomach. This opens, and then the cardiac end of the œsophagus, becoming passively dilated, receives as much of the fodder as it will contain. The cardiac aperture now becoming closed, the bolus thus shut off is propelled by the reversed peristaltic action of the muscular walls of the œsophagus into the mouth, where it undergoes the thorough mastication which has been described."

In connection with this it may be remarked that fuller illustration by figures of the organs of digestion, circulation, and respiration in different animals seems desirable in the Manual.

Of the 110 woodcuts contained in the Manual, two-thirds are original, while the remaining third (37) are borrowed from other authors, whose names are mentioned in the preface.

For so complex a subject as the osteology of the skull, as well as perhaps in several other parts, some extended table of the bones, with the letters of reference employed throughout the work, would afford considerable assistance to the student.

It might also be advantageous in an elementary work of this kind to have added select references to works for fuller study, and a glossary of (at least unusual) terms.

In concluding this notice we repeat that the Manual is in every way worthy of its learned author, and calculated to be extremely useful in promoting the study of Comparative Anatomy and Zoology on sound principles. The work cannot fail soon to go to a second edition, when the author will have considered the expediency of such additions as we have ventured to suggest, or of others of which he approves, and which he has doubtless been deterred from including in the present work from the desire to bring it within as narrow a compass as possible. We may also express the hope that the publishers have made arrangements for the speedy publication of a similar Manual of the Anatomy of the Invertebrate Animals.

ALLEN THOMSON

NOTES
